All these dealt with the complex variable. Later came Cantor's theory of sets of points, leading to a great development of the theory of functions of a real variable. The name of Carathéodory is familiar to mathematicians as the author of a masterly treatise on the real variable. But the work under review is of quite a different nature; it can be described roughly as an introduction to a modern version of Riemann's geometrical ideas, freed from their original weaknesses, so that this approach can now be considered as firmly founded as the Weierstrassian. The main supports of this new version are Schwarz's theorems on conformal representation and Montel's concept of normal families of functions. These are used in conjunction with several modern developments, some due to the author himself, to give a clear and attractive exposition of fundamentals, though not including the general theory of Riemann's surfaces, of algebraic functions, or of uniformization. Although designed primarily as a text-book for students, some parts will be new and interesting even to the expert. The author died before it was published; but he had the satisfaction of seeing all the proofs, and his failing health would never have been suspected from the polished excellence of the work.

The division of the work into two volumes of unequal size, which is stated to be for the convenience of students, does not correspond to any real break in the continuity of the argument, and must have added to the cost of the work, which, at the present rate of exchange, is very high indeed in Great Britain. The first volume is divided into five parts, and the second volume into two more parts; each part is subdivided into three or four chapters. The first part begins with complex numbers, but takes an unexpected turn with the transition to spherical and non-Euclidean geometry. Emphasis is laid upon Ostrowski's *chordal difference* of two complex numbers, which is much used in the later pages, as it enables the point at infinity to be treated on the same footing as ordinary points. The second part gives a brief enunciation of such parts of the theory of sets of points as are needed in the later pages; for proofs the student is referred to the author's "Reelle Funktionen". The third part deals with analytic functions, including Cauchy's theorem, the maximum-modulus theorem, Schwarz's lemma, Poisson's integral, harmonic functions and meromorphic functions. The fourth part deals with the generation of analytic functions by limiting processes, using the somewhat unfamiliar ideas of *continuous convergence* and *limit-oscillation* to treat normal families of functions. These modern ideas precede the much older theorems of Taylor, Laurent, Mittag-Leffler, and a very brief treatment of the calculus of residues. The English-speaking reader may be puzzled why books in his own language contain so many examples, worked and unworked, on hese topics, while Carathéodory's book contains none. The fifth part deals with some special functions, namely, the exponential and trigonometrical functions, the logarithm and general power, the gamma function, and Bernoulli's numbers.

Turning to the second volume, the sixth part begins with a discussion of functions the moduli of which in a certain domain do not exceed unity, and in particular those of which the moduli are equal to unity at every point on the circumference of a circle of unit radius. After the important theorems of Pick, Jensen, Julia, Lindelöf, Fatou and Riesz, the way is clear for a rigorous treatment of conformal representation. The seventh and last part opens with analytic functions of two or more variables and some existence theorems on differential equations. It then applies the conformal transformation of a triangle, the sides of which are circular arcs, to deal with the hypergeometric function and its differential equation. Next come the Schwarzian triangle-functions and the modular function. Finally, there is a discussion of essential singularities and the theorems of Landau, Schottky, Picard and Montel.

The work is beautifully printed, as well as beautifully written, and may be warmly commended to those who can afford to buy it.

THEORY OF PROBABILITY AND STATISTICS

Introduction to the Theory of Probability and Statistics

By Prof. Niels Arley and Prof. K. Rander Buch. (Applied Mathematics Series.) Pp. xi+236. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 32s. net.

THIS work is a translation (with a few alterations and additions) of the third Danish edition of a book which has already proved very successful in the country of its origin. For the most part, the translation has been carried out very well.

The two authors are well known for their achievements in different branches of the subject: Niels Arley has made important advances in the theory of stochastic processes and in its application to the problems of cosmic radiation, and K. R. Buch is best known for his work on the range of values assumed by a measure-function on an abstract space. When a physicist and a pure mathematician join forces, the outcome is sure to be interesting; in this case it is a highly individual book which should do good work in familiarizing students of the natural sciences with the ideas, notations and techniques of the modern theory of probability. Its excellence as an introductory text-book for physicists may be illustrated by mentioning that Poisson's distribution makes its first appearance in connexion with the Poisson process (stochastic processes in general appear on p. 48, and the ergodic theorem four pages later). No attempt is made to burden the book with proofs of the central-limit and allied major theorems; but their substance is sufficiently indicated, and the reader is given an accurate and clear picture of what can be expected from the mathematical theory. He will, if serious in his intentions, find this a useful introduction to a detailed study of the more comprehensive work by Feller.

As a text-book on statistics as opposed to probability theory, I found the book much less satisfactory, and it is perhaps a pity that a third collaborator was not found to prepare the 'Fisherian' chapters. For example, there is no mention of the analysis of variance, of the χ^2-test for 'goodness of fit' or of two-by-two contingency tables. In a subsequent edition there is much that could be done to improve these sections of the book; the first half is so good that such an improvement would be well worth while.

David G. Kendall

Elsevier's Encyclopædia of Organic Chemistry

Edited by F. Radt. Series 3: Carboisocyclic Condensed Compounds. Vol. 12B: Naphthalene, A, Compounds containing One Naphthalene Nucleus; Oxo-Compounds (except Quinones). Pp. xxxv+2189–2716+Ind. 62. (New York and Amsterdam: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1950.) £14 to subscribers to whole work.

This fourth part of Vol. 12B takes the naphthalene section of the "Encyclopædia" a stage further (see *Nature*, 167, 916; 1951). It is characterized by the customary excellence of production and freedom from error, and is concerned with aldehydes and ketones containing a naphthalene or hydronaphthalene nucleus. The various compounds are catalogued and their physical characteristics, methods of preparation and chemical reactions are discussed in the stereotyped way. Many of the compounds included in this part are in the nature of intermediates, without great intrinsic interest, and there is perhaps less to appeal to the reader generally interested in organic chemistry than in some of the preceding parts. There are, however, some interesting accounts of the sesquiterpene ketones, such as eremophilone and the cyperones, of the α- and β-tetralones, and of the stereoisomeric α- and β-decalones and their derivatives. The ketonic derivatives of the various hydronaphthalenes are rather scattered throughout the volume, and the tabulated summaries of these given at the beginning will facilitate rapid reference.

Apart from these ketohydronaphthalenes, most of the compounds treated in this part are, of course, compounds in which the carbonyl function is not an integral part of the naphthalene nucleus, but forms a separate attachment. There are, for example, the α- and β-naphthaldehydes and their derivatives, and the various groups of naphthyl ketones, including diketones in which the carbonyl groups are either present in a single side-chain or in two substituents. Included in this volume are the non-enolizable *gem.*-substituted derivatives of the ketonic forms of the naphthols, especially those formed from 1-substituted-2-naphthols. The production of such ketones is a warning against too sweeping generalizations in theories of aromatic substitution. J. W. Cook

The Solidifications of Castings

A Review of the Literature. By R. W. Ruddle. (Institute of Metals Monograph and Report Series, No. 7.) Pp. 116. (London: Institute of Metals, 1950.) 10*s*. 6*d*.

Imperfections present in castings or ingots persist, at any rate in large measure, despite any heat or mechanical treatment to which the metal may afterwards be subjected. It is therefore in the highest degree desirable that the factors which control the original solidification of the metal should be understood. Even to-day the production of castings is in large measure a matter of trial and error, combined with traditional experience.

In recent years, however, much attention has been paid to the scientific aspects of the problem, both on the empirical and fundamental sides, and the object of this monograph is to provide a critical review of the existing literature. Part 1 covers, in a general way, the work which has been done towards the practical application of scientific principles; the importance of directional solidification is discussed, and the means available to attain this end are considered. In Part 2 a review is given of the more fundamental work concerned with the rate of abstraction of heat and of solidification, and, although at the moment mathematical analysis has probably yielded results of less importance when applied to non-ferrous castings than to steel, possibly due to the longer freezing ranges, it can, in conjunction with experimental methods of studying the problem, be of undoubted value. The researches discussed in Part 2 and the conclusions drawn therefrom are briefly summarized in Part 3, and an appendix provides details regarding the thermal properties of metals and of the materials from which the moulds are made.

This review, prepared originally for the British Non-Ferrous Metals Research Association, fully upholds the high standard now expected from the Monographs of the Institute of Metals, and the author is to be congratulated on a most useful piece of work excellently carried out. F. C. Thompson

Scientific and Learned Societies of Great Britain

A Handbook compiled from Official Sources. 57th edition. Pp. 228. (London: George Allen and Unwin, Ltd., 1951.) 30*s*. net.

After a lapse of eleven years the compilation of "Scientific and Learned Societies of Great Britain" makes a welcome return to take its rightful place on the easily accessible shelf among other reference sources of British scholarship and learning. This handbook was previously known as the "Year-book of Scientific and Learned Societies", and under that name it has been published, almost continuously for more than fifty years, by Charles Griffin and Co., Ltd., the last issue appearing in 1939. After the end of the Second World War, the British Council acquired the rights of publication and is responsible for editing the present work. If praise be needed, it is sufficient to say that the book is every bit as good as its predecessors.

Part 1 is a new feature of this book and deals with the organization of scientific research in Great Britain. It gives the names and addresses of the main research organizations administered by the Department of Scientific and Industrial Research, Medical Research Council, Agricultural Research Council and the research associations. An interesting chart has been constructed outlining schematically the relationship of the various bodies in Great Britain engaged in scientific research.

Part 2 of the book, which forms about five-sixths of the two hundred-odd pages, is on the lines of the previous issues. It is divided into fifteen sections as follows: general science; mathematics and physics chemistry; biology and microscopy; medicine agriculture, horticulture, forestry and veterinary science; engineering and architecture; geography geology and mineralogy; archæology and history anthropology and sociology; law; economics statistics and political science; literature and fine arts; town and country planning and public amenities; other societies. The sections are divided into the regions of London, counties, Scotland, and (where applicable) Wales and Northern Ireland Within these regional sub-divisions more than six hundred societies are listed alphabetically, giving the objects of the society, principal officers, membership subscription, meeting times and publications.

An index of subjects and names of societies completes the volume.

THE BRITISH CONTRIBUTION TO SCIENCE AND TECHNOLOGY IN THE PAST HUNDRED YEARS*

By H.R.H. THE DUKE OF EDINBURGH, K.G., F.R.S.
President of the British Association

To mark the opening of this year's meeting, His Majesty The King has been graciously pleased to send the following message:

> I shall be glad if you will express to the members of the British Association for the Advancement of Science my appreciation of their having once more honoured a member of my family by inviting him to be their President.
>
> I trust that this year's meeting of the Association will further the development of Science for the benefit of mankind throughout the world, and prove an encouragement to all those men and women who are so devotedly working for that end.

On your behalf I propose to reply in these words:

> The Members of the British Association for the Advancement of Science assembled at Edinburgh send Your Majesty their humble duty and their loyal thanks for Your Majesty's Patronage of the Association and your gracious message of encouragement.
>
> I am to assure Your Majesty that the development of Science for the well-being of Your Majesty's Realm and for the general welfare of mankind is the constant object of the Association.
>
> We will strive with all humility and with the grace of God to apply the blessings of scientific and technological improvement to the problems which face us all to-day.

In Aberdeen in 1859 my great-great-grandfather started his address to the British Association with these words:

"Your kind invitation to me to undertake the Office of your President for the ensuing year could not but startle me on its first announcement. The high position which Science occupies, the vast number of distinguished men who labour in her sacred cause, and whose achievements, while spreading innumerable benefits, justly attract the admiration of mankind, contrasted strongly in my mind with the consciousness of my own insignificance in this respect."

I cannot improve on this to express my own feelings; but, like him, I reflected upon your invitation and came to the conclusion that it is just as an outsider, a layman so to speak, that I can be useful to you and to science. This very invitation seems to me to demonstrate that science is not a magic circle and that you wish us to enter your confidence. In return the least I can do is to show our appreciation of the work of scientists and to give you a layman's impression of the march of science in the past hundred years. I crave your indulgence if I have drawn any false conclusions and I hope that during the meetings which will follow this one, the experts will take the opportunity to make any corrections.

The Prince Consort had very much less reason to be modest about addressing you than I have, because this year we celebrate the anniversary of the Exhibition which was his greatest achievement, and an event which had an untold value to science. Let us hope that this year's Festival will be judged a worthy successor and an inspiration for the future. I am proud to pay tribute to this man who saw so clearly the part science was destined to play in the future of this country, and my address is largely the story of the fulfilment of his hopes.

The Starting Point

In a review of British science and technology, 1851 is a convenient starting point for two reasons. First, the Exhibition of that year can be regarded as a gigantic stocktaking of the national resources and technical skill; secondly, because it marked the end of the Industrial Revolution and the conversion of Victorian England to the policy of industrial expansion on which our future still depends. The period as a whole saw the climax of our industrial supremacy and its inevitable decline when countries with greater resources and population learned from us the lessons of the mechanization of industry. It also covers the birth and growth of the new concepts of modern science.

Social conditions of a hundred years ago were, generally speaking, the outcome of the Industrial Revolution, but with all the traditions of the England of agriculture, cottage industry and small market towns. The population of 20 millions was growing fast but still small compared to our 50 millions of to-day. Education was limited to a minority and was almost entirely classical, so the new profession of engineering had to draw its recruits from a different sphere—that of self-educated men. A new wealthy class was growing up in the commercial world to rival the old aristocracy. There was unbounded optimism about the future and ample scope in commerce and industry to attract all intelligent and enterprising men. The number of poor was on the increase and their conditions were deteriorating because, as yet, no social conscience had grown up to replace the patriarchal responsibility of the landowners and master craftsmen.

In the domestic field, lighting was by candle and oil lamps, cooking and heating by coal or wood in ranges or open fires with the consequent enormous waste of energy. Food had to be fresh or crudely preserved, and thus needed to be produced locally. In health and hygiene the figures speak for themselves. In 1851 the infant death-rate was 150 per 1,000 live births compared with 25 per 1,000 to-day. Anaesthetics, antiseptic surgery, biochemistry, tropical medicine, were all virtually unknown or in their infancy. Psychology had not yet achieved independence from philosophy on one hand and physiology on the other.

---

* Presidential address delivered at Edinburgh on August 8.

This was the age of the practical engineer and of processes arrived at by intuition born of experience and by trial and error. Technology was concerned with the application of steam-power, with metallurgy and the working of metals for various purposes, and with the production of machine tools and precision machinery. Men were already turning their minds to other types of engines, and the internal combustion engine was in the process of development.

Scientists, while continuing their search for the secrets of Nature, were beginning to turn their attention to exploring the empirical developments of industry. Their numbers as yet were small, the endowments for research were negligible and much of their work was carried out in the watertight compartments of the different sciences. But the seed had been sown, and it was not long before scientists and engineers were preparing the way for the great technological harvest of the twentieth century.

The Conditions

The changes brought about in the lives of men and women in the last hundred years have been greater and more rapid than during any other period in history, and these changes have been almost entirely due to the work of scientists and technologists all over the world. They have not only affected the way of living of all civilized peoples but have also vastly increased our knowledge about ourselves, the earth we live on and the universe around us. I cannot emphasize too much that the sum total of scientific knowledge and technological progress is an international achievement to which every civilized country has made some contribution.

Now before considering the contribution of the British Commonwealth, I should like to sketch what appears to a layman like myself to have been the main influences on the course of scientific and technical achievements since 1851 and their relation to one another.

The great stimulus of the 1851 Exhibition created a growing interest in technical education and research, followed by a widening of the scientific horizon which was soon to find expression in borderline subjects. For the next fifty years science advanced rapidly; but in most fields there was a wide gap between science and industry. Electricity was an exception, and the groundwork was already being laid for the electrical revolution of the Victorian age. Medicine was on the verge of breaking away from medieval practice and taking the first steps towards its modern pattern, while British colonial development stimulated the study of tropical disease.

Between 1851 and 1870, practice, in many industries, was ahead of science, and in that period the large number of inventions of the Industrial Revolution were progressively improved and widely applied. These inventions, which added so much to our industrial production, were mainly the work of British genius. They were of great economic advantage to this country and were quickly exploited commercially. New factories and plants were built to include the very latest ideas, and with the expansion of industry came the demand for more and more new ideas and greater efficiency. This demand was a direct stimulus to technological invention as well as an indirect stimulus to science. We are still struggling with the social results of this vast expansion.

From 1870 to 1890 the highwater mark of British industrial expansion, as compared with other countries, had been reached and the competition of the United States and Europe was just beginning to be felt. But the lack of serious competition hitherto had bred a feeling of over-confidence and satisfaction in the methods and processes employed. The result was a conservative attitude towards technical change and, particularly in the older industries, neglect of scientific research. Accumulation of wealth and the income from foreign investments in any event made the country as a whole less dependent on the efficiency of her industries. Concurrently a subtle change occurred in the type of British exports. So far the products of our machinery, such as rails and rolling stock, had been shipped abroad for immediate use; but now machines themselves were exported to do their work in the factories of Europe and America instead of in Britain. The result of this was to intensify foreign industrial competition between 1890 and 1914; but with the increasing demands from the Colonies the volume of British exports was not greatly affected.

Then came the critical years of the First World War, bringing a realization of the part science must play in the industrial and military strength of the nation. For the first time in history a real attempt was made to enlist the services of science in the war effort, and the Department of Scientific and Industrial Research was founded to further the application of science in industry through Government laboratories and through research associations.

The effects of these measures appeared clearly in the inter-war years, when there was a marked swing of education from classics towards science. Coupled with this, the War had directed the attention of many research scientists to practical objectives, so that after the War there was a rapid expansion of industrial research. Scientific progress was no longer confined to the work of a few brilliant individuals, but came also from teams of research scientists each working on different parts of the same problem. It was during this period that many new commercial research laboratories grew up, employing scientists to discover new processes and materials connected with their industry as a direct weapon of competition.

The War had also shown a great weakness in our dependence on foreign production for many vital articles, such as dyestuffs, scientific instruments and optical glass, in the manufacture of which scientific research played an essential part. This weakness was remedied with the help of the Key Industry Import duties, which gave the necessary support and encouragement to the establishment of these industries at home.

It is true that manufacturers in some of the older industries still clung to traditional methods in spite of the pressure of competition from America and other countries. In this connexion it is significant that the history of production engineering after 1890 is almost entirely confined to the United States.

It was, however, a period of rapid development in Britain. The invention of the internal combustion engine and the pneumatic tyre had opened new branches of industrial engineering, and the demand for fuel for motor-cars and aircraft gave birth to the new technology of oil. In the electrical, chemical and aircraft industries, science was fully enlisted in the fields of electronics, synthetic fibres, plastics, aerodynamics and light alloys. Consequently the outbreak of war in 1939 found us in a much stronger position to meet the immense demands it made on all branches of technology for new gadgets, machines and weapons. From the outset science in all its forms and branches was harnessed and completely co-ordinated with the war effort. It was only the intimate partnership of science and engineering with the staffs of the Fighting Services that enabled us to meet swiftly and effectively the ever-changing menace of total war.

The tremendous demands on our industries had some good after-effects. Once again these demands revealed weaknesses where our industrial capacity was out of date. The realization of this has initiated comprehensive reconstruction on most modern lines. The almost complete absence of income from our foreign investments has forced us to rely once more on our capacity to make the goods the world requires. Our industry and productivity have shown a wonderful improvement; but there is still a lot more that can be done. The rate at which scientific knowledge is being applied in many industries is too small and too slow. Our physical resources have dwindled; but the intellectual capacity of our scientists and engineers is as great as ever, and it is upon their ingenuity that our future prosperity largely depends.

The Contribution

I would now like to make a brief survey of the British contribution to natural knowledge and technology and pay a tribute to some of the great men of science of the past hundred years.

In some branches almost the whole story can be told, since one problem after another has been solved by British scientists. In others there are many blanks and gaps where the vital links in the chain were forged abroad. But looking at the whole vast field of abstract and practical science there can be no doubt that during this period the contribution of the British Commonwealth has been of outstanding importance.

Our knowledge of the stars, the heavens, and our place in the universe has increased steadily through the centuries; but since 1851 some of the most important links were supplied by such men as Eddington, Jeans and Milne in their work on mass, luminosity and stellar evolution. Huggins made a great contribution with his application of spectrum analysis to astronomy, and Lockyer's discovery of helium in the sun had a significance far beyond the realms of astrophysics.

Coming nearer to the earth, the work of Abercromby and Shaw on the behaviour of the earth's atmosphere in the troposphere started the scientific study of weather and weather prediction, and Appleton's research into the ionosphere extended this to the upper air.

Chemistry has fascinated man from the earliest times, and vast progress has been made in the past hundred years both in knowledge and theory. Much fresh ground was broken by Crookes by his work on spectra, his discovery of thallium and of 'radiant matter' known later as cathode rays. Long after everyone was quite sure of the composition of the air, Rayleigh found another ingredient which he called argon and so started the hunt for other inert gases. In organic chemistry both Perkin and Robinson have added enormously to our knowledge of the structure of carbon compounds, and to our power to copy natural products synthetically. The development of X-ray analysis by the two Braggs, father and son, has given us a means of finding the actual arrangement of the atoms in the molecule and has revealed the accuracy of the chemists' conclusions about the architecture of molecules based on their reactions with one another. This is a most striking example of the power of the theoretical and practical scientist to penetrate Nature's secrets.

Going beyond the chemist and his molecules, we come to the physicist and the study of even smaller particles. Thomson's discovery of the nature of the electron was the first attack upon the integrity of the atom. Next, thanks to Rutherford's brilliant research and keen intuition, came the nuclear theory which revolutionized our ideas of matter. To prove it, he was the first man to succeed in the transmutation of an element. It is appropriate to mention Moseley's work on the X-ray spectra of the elements, as it already showed such great promise, before he was killed at Gallipoli.

Parallel with this activity in the physical sciences there occurred a technological revolution of even greater scope and variety. The Darbys of Coalbrookdale were the lineal ancestors of Bessemer, Thomas and Siemens, and the whole technology of metals. First, cheap cast iron followed by cheap steel, then steel from phosphatic ores, completely changed the materials available to engineers, shipbuilders and architects. Scientific metallurgy can be said to have started when Sorby first applied a microscope to the surface of metals. The way was opened for the investigation of the metallic alloys which came in quick succession from developments in which Hadfield and Rosenhain made outstanding contributions.

It was not long before the possibilities of these new materials were recognized, and the great majority of the mechanical developments of the period were due to new alloys which could withstand higher stresses. But before these materials could be fully used, Maudsley and Whitworth had to lay the foundations of production engineering, and Mushet had to do pioneer work in developing tungsten steel as the first high-speed cutting tool.

The reciprocating steam engine of the Industrial Revolution was the main source of power until Parsons invented the steam turbine, which revolutionized large-scale power production on land and sea. But that was not the only source of power to rival the push-and-pull engine. The internal combustion engine, in which Dugald Clerk and Akroyd Stuart were among the early pioneers, has proved to be a formidable challenger in many fields. In marine engineering, Froude's work on hull forms and propellers enabled the full benefit of the new prime movers to be reaped at sea.

Here I wish I could mention early British pioneers of motor-vehicles; but, as is well known, restrictive legislation drove the development of the motor-car abroad, until the repeal of the speed limit in 1903 gave scope to the genius of Royce, Lanchester and Ricardo. In place of the motor-car, however, we have Lawson to thank for the invention of the safety bicycle; and all wheeled vehicles except those running on rails owe their rapid development to Dunlop's invention of the pneumatic tyre. The material required for this started the vast natural and synthetic rubber industry, and has made famous the name of Wickham for a brilliant feat of smuggling, when he brought the rubber seeds from Brazil to Kew, from which sprang the rubber plantation industry of the East.

In flying, the names of the pioneers and their feats are legion, and more than in any other mechanical science the development of aerodynamics has been shared by many nations; but Lanchester's vortex theory was one of the stepping stones to powered flight, and the achievement of Alcock and Brown in making the first Atlantic flight in 1919 speaks highly for the tremendous scientific and technological background of flying in Great Britain. Of outstanding importance and consequence was the genius which Mitchell brought to aircraft design, and, more recently, Whittle's pioneer work has given us the lead in jet engine production both for civil and military use.

Following on the immense progress in metallurgy and mechanical engineering, the most far-reaching development of the period has been that of electricity and electronics. Although the key discovery belongs to Faraday in an earlier period, the second founder of the science is undoubtedly Clerk Maxwell, with his classic treatise on electro-magnetism. The use of electricity for domestic and industrial purposes was helped by Wilde's development of the dynamo and then by Swan's incandescent lamps. Wheatstone and Kelvin pioneered the use of electricity for communication by their work on line and cable telegraphy. Wireless telegraphy soon followed, and the work on tuned circuits by Lodge, and Marconi's many brilliant developments made in Britain with the General Post Office and the Navy, soon made radio a practical proposition. Heaviside and Appleton made further contributions on the propagation of radio waves. It is interesting to see that the technique used by Appleton in his pulse-ranging on the ionosphere and upper layers was later developed by Watson-Watt into radar, which is now almost indispensable to airmen and seamen all over the world. Here Randall's development of the magnetron for high-frequency radar was one of the major contributions to the Allies' equipment for war.

Television has a wide parentage, but Baird's name will always be linked with the first successful pictures.

Another great innovation of this hundred years was the discovery and development of plastic and synthetic materials. The story starts with Parke's discovery of celluloid and Cross and Bevan's manufacture of viscose which gave birth to the rayon industry and the many later types of synthetic fibre. Perkin's mauve, first of the aniline dyes, and Kipping's new silicon compounds were, however, disregarded by industry in Great Britain. But we see to-day a change of heart in the development in our industrial laboratories of two new plastics, 'Perspex' and polythene, with almost an unlimited range of applications in the air, on the ground, and at sea.

The effect all this has had upon the citizen varies naturally with where and how he lives; but basically it has given him reliable light and heat in his home, push-button communication with almost any part of the world and home entertainment of a high quality. His transport on land, at sea, and in the air is quick, comfortable and clean. In addition, he has a vast range of materials with which to clothe himself and to furnish and embellish his home. Almost more important, these developments have brought about a complete change in his conditions of work.

But if the citizen has benefited, so too has science from the great array of new techniques that have been invented and the new tools with which the scientist and technologist can burrow, hack and worry at the growing mountain of problems to be solved.

So far I have dealt with the physical sciences. Now I would like to turn briefly to the biological and psychological sides, which after a slow beginning in Great Britain have made increasingly rapid progress.

The whole field of biological science in this period is overshadowed by the works of Darwin presented in his "Origin of Species" and "The Descent of Man". Nothing has done so much to widen man's thoughts as his conception of evolution as the great law controlling living things, "that progress comes from unceasing competition, through increasing selection and rejection".

In the basic study of living things some of the most important contributions from Britain were the pioneer work of Francis Galton and William Bateson in the field of heredity, Sherrington's work on the integrative action of the nervous system, and Dale's and Adrian's contributions to our knowledge of the transmission of nervous impulses.

The science of biochemistry is relatively new and Gowland Hopkins was its founder in Britain. His discovery of the significance of accessory food factors, leading up to the recognition of vitamins, started the modern science of nutrition. Other landmarks were Bayliss and Starling's recognition of the part played by hormones in the blood stream, followed by Banting and Best's isolation of insulin, and Harington's synthesis of thyroxin in Edinburgh.

Fleming, working on mould cultures, discovered the antibacterial properties of penicillin, and later Florey and Chain, at Oxford, found that penicillin could be extracted in a highly purified form, and used it to treat human disease.

Modern surgery can be said to have been born in Scotland, with Simpson's discovery of the use of chloroform as an anaesthetic and Lister's antiseptic technique based on Pasteur's bacteriological discoveries. A further advance of the greatest value to surgery as a science was Macewen's aseptic technique, which made surgery clean and safe, followed by his classic work on the brain and spinal cord.

If Lister was the father of modern surgery, then Manson was the father of tropical medicine, and it is particularly in this field that the British contribution has led the world. The discovery by Ross that malaria is carried by the anopheles mosquito and, much later, the work of Fairley in Australia on its prevention and cure, have been of the greatest benefit to mankind. Bruce will always be remembered for his discovery of the part played by the deadly tsetse fly in the transmission of sleeping sickness and his work on Malta fever. Finlay, Adrian Stokes and Hindle stand high among the names linked with the study and prevention of yellow fever.

These were all vital efforts towards the prevention of sickness; but there is another aspect of medical practice in which the Commonwealth has taken a leading part—the promotion of health. It was Sir John Simon, the first medical officer appointed to a central authority, who made a careful statistical study of the causes of sickness, with the view of taking effective measures for the health of the community at large. Through his leadership, health services have been provided in regular stages throughout the country. At first these were largely aimed at providing pure water, effective sanitation, and the abolition of slums; but since the beginning of the present century the *personal* health services, especially in the case of mothers, babies, and school children, have become national in scope and lead the world.

There are two other fields in which the biological sciences play a major part. The first is in the preservation of food and in nutrition, which has had the most profound economic and social effects. The ability through freezing, drying and canning to import large quantities of food has enabled a rapidly increasing population to maintain and increase its standards of living, which would have been impossible had it been dependent on British agriculture alone. The scientific study of nutrition has made it possible to improve the health of the population and in war to feed the people with the minimum of waste.

Mort had the first freezing works in the world at Sydney, and was a pioneer in refrigeration; but success in transporting meat to Britain had to wait for the development of more reliable refrigerating plant. Since 1918 the Food Investigation Laboratories of the Department of Scientific and Industrial Research, of which Sir William Hardy was the first director, have established the basic biological knowledge on which the storage and transport of meat, fish and fruit are now largely based.

The second field is in agriculture, where in order to compete with cheap foreign foods the most successful farmer is one who enlists the full assistance of science. Lawes, who discovered how to make and use superphosphate, and started the great fertilizer industry, was quick to realize this. He founded Rothamsted, now the oldest agricultural research station in the world, and there he and Gilbert carried out the first scientifically controlled field experiments which laid the foundation of agricultural science. Later, Biffen's pioneer work in plant breeding at Cambridge became one of the greatest contributions to the problem of feeding the world's growing population. He showed how it was possible to breed strains of wheat combining resistance to disease with high yields and good milling properties. In the field of animal breeding, the foundation of the most important aspect of British agriculture to-day, I will mention among the many investigators only Cossar Ewart and Crew, who did so much to advance its scientific study here in Edinburgh. The mechanization which was to revolutionize farming in all parts of the world was also under way and Britain was playing a leading part. The reaping machine, for example, was invented by Patrick Bell in 1826 although it was not manufactured until 1853.

There is no need to point out the effect which all these improvements, discoveries and inventions have had on society. It is this group of biological sciences which have had the most far-reaching social results, and it is particularly during and since the Second World War that it has been possible to exploit them.

There is one science which I have not yet mentioned. It is both the youngest science and the oldest problem. The study of man's mind was the province of the philosopher until the middle of the nineteenth century, when it separated from him and began its independent existence as the science of psychology. The foundations were not laid in Great Britain; but important contributions were made, both from the biological and the philosophical sides, by men like Ferrier, Bain and Ward. Sully's work on child psychology was the first of its kind. But probably the most outstanding figure in this country was Galton, whose teaching is widely respected in all psychological laboratories, and who was the first to develop an interest in the mental differences between individuals—a field in which British psychology has made some of its greatest contributions. Again, it is only recently that full practical advantage is being taken of the progress made in this branch of science; but the results of that application may be as important as the many more easily understood developments in the purely physical world.

The Implications

The story of the British contribution to science in the past century is indeed impressive, and I am very pleased to have this opportunity of paying tribute to the men whose achievements I have been discussing. But this story would not be complete without studying the wider implications of their work and examining some of the lessons to be learnt from it.

The concrete measurement and indirect effect of all scientific effort is the general improvement in the conditions in which people live and work; it is in the improvement in health, in the expectation of life and standards of living; the latter including not only food and clothing, but also housing, home comforts, medical care, education, books and newspapers, recreations and travel facilities. In every one of these directions the progress that has been made has amounted to a revolution.

Not all this springs directly from science and invention. Much has been due to the politicians and administrators, and behind them to religion, morals, education, art and the complex influences which we call culture. But even there science has stood beside the authors of progress to advise, to help and sometimes to guide.

Now as science and technology are so vital to the future strength and prosperity of the British Commonwealth, the great problem is to discover the conditions under which they are most likely to flourish. The records show that both depend very much on co-operation, and upon the linking up of a long chain of discoveries, one with another; so that it is quite exceptional for the credit of a great advance to belong to one man or even to one country, although it will always require the flash of inspiration to weld the links into the chain. To-day the development of team-work in laboratories has made this truer than ever. For many reasons, but principally because of the increasing complexity of research and its cost, such team-work is becoming more and more the rule. We need not repine at this; but it would be a disaster if the individual inquirer working in his own laboratory were discouraged out of existence.

While the quality of scientific work is determined by the quality of the scientist, the quantity of scientific output is determined by the money available. The rapid progress of science in Britain has owed much to the growing support and sympathy of government and individual benefactors and to the endowment of research by industrial corporations. However, the basic discoveries that mark the great advances depend on the accident of individual genius and are not at our command.

The scope and intensity of the progress of applied science and technology, on the other hand, bear a close relationship to the circumstances of the time. Technology, as the combination of scientific knowledge with the practical ability of the inventor to apply that knowledge to the solution of particular problems, comes into play with any new discovery of scientific fact. The latest particle of truth is then developed, according to the circumstances of the time, for military, commercial or medico-social purposes. It is a sad reflexion that the urgent demands of modern war can produce advances that might otherwise take many years to develop, especially in the costly and uncertain experimental stages.

The rivalry between large commercial undertakings, using science to improve their products or processes as a direct means of competition, has produced a steady flow of improvements and developments. However, the fruits of this form of scientific work are sometimes open to considerable misuse. The discoveries of these commercial laboratories may be kept secret, and in some cases a number of teams may be working on the same problem, which may have already been solved elsewhere. The buying up and suppression of patents and discoveries to protect equipment from becoming obsolete has also been known to happen. I am glad to see, however, a change of outlook in the growing quantity of publication of the results of industrial research.

It would seem that science has become so well established that nothing can stand in the way of its natural growth. This is far from the truth. Since the earliest times the natural conservatism of laymen has acted as a powerful brake to the adoption of new ideas which do not rigidly conform to his notion of the correct order of things. In its most violent form it will produce unreasoning anger, utter disbelief in face of the clearest evidence or provoke plain ordinary laughter. The storm raised by Darwin's "Origin of Species" is an excellent example where even scientists failed to keep an open mind.

The position seems better to-day, and I am sure that Sir Harold Hartley, our immediate past president, spoke for all scientists when he said: "To-day, with our greater understanding, there is humility in the minds of all scientists. The further we penetrate into Nature's secrets the more clearly we see the ever-receding frontiers of knowledge."

The resistance towards anything new or unexpected is balanced, on the other hand, by bursts of enthusiasm that some particular discovery or invention will see the end of all our troubles. The belief in the philosopher's stone seems to be just as great as ever.

As the front of pure science has advanced, so its lines of communication to practical exploitation have got longer and longer. The time was when the whole process of discovery, application and exploitation could be achieved by one man. In our time a great army of scientists, technicians, inventors, designers and production engineers is required to keep the lines of communication open. Quite how important some of the members of this follow-up team have become is not always appreciated. In his presidential address in 1948 Sir Henry Tizard emphasized this point when he said: "All depends on good design and production. Our weakness in the war was not to be found in what was best to do, nor in the scientific work of how to do it. It was when the stage of design and production was reached that we fell short of the best standards."

This was true already when Whitworth invented the screw micrometer, which was afterwards put into production in Germany and the United States, and up to the First World War all micrometers had to be imported into Britain.

To Prof. Kipping of Nottingham goes the credit for the basic work which led to the development of silicones in Russia and the United States, and yet until this year we have been dependent on imports from the latter of marketable silicone products.

There are many cases in the Navy where a piece of apparatus has been used operationally exactly as the inventor put it together, with all the resulting disadvantages in maintenance and efficient operation. The limitation in performance, except in some cases, is practical as opposed to scientific. Where the basic scientific principles are known by all nations the advantage lies in the good design of equipment for practical use.

A more general and far-reaching matter for concern, and possibly the most vital factor affecting the industrial application of scientific research, is the lack of a co-ordinated system of scientific and technological education in Britain. Excellent as they are, the existing institutions, which have grown up to meet particular circumstances, do not produce anything like enough trained technologists to meet the urgent needs of scientific development in industry and to provide leaders for the future. It is to be hoped that the new and rather uncertain science of education will develop sufficiently quickly to point the way to a speedy solution of this problem.

The shortage in Britain of "personnel trained and eager to apply scientific knowledge and scientific methods to practical ends"—as Sir Ewart Smith said last year—is only one of the many shortages which the world is now facing. Among them are food, non-ferrous metals, steel alloy metals and sulphur. These very shortages are due to the scientific complexity of present-day life, and it is only by science that they can be overcome. Naturally, there are many ways of tackling this problem; but the most obvious are: first, by improved design to secure economy in production and the minimum use of scarce materials; secondly, by the development of substitutes made from raw materials which are still abundant; thirdly, by the reclamation of scrap and improved methods of using low grade ores; finally, the development of renewable raw materials such as timber to satisfy the world demand for cellulose. Some of these shortages are partly due to the huge inevitable waste of war and its consequences, and partly to the lack of any comprehensive survey of the world's resources and requirements. It is only by an accurate knowledge of the world's resources that we can foresee the scope and magnitude of the future problems which science and technology have to meet and which only they can solve.

It is, therefore, good news that the Economic and Social Council of the United Nations has resolved "to promote the systematic survey and inventory" of those resources which are not already covered by the Food and Agriculture Organization.

We have evolved a civilization based on the material benefits which science and technology can provide. The present shortages are a timely reminder of the slender material foundation on which our civilization rests, and of our dependence upon science and technology.

The Conclusion

The pursuit of truth in itself cannot produce anything evil. It is in the later stage when the facts dug up enter the process of application that the choice between the beneficent and destructive development has to be made. It is quite certain that it is an exception if any particular discovery cannot be used equally well for good and evil purposes. Happily the beneficent exploitation of scientific knowledge has kept pace with its destructive application.

In a mid-century article *The Times* put it this way: ". . . It has been an age of great achievement. The lines of progress in which the Victorians trusted have been pursued farther and faster than they foresaw. Scientific discovery, from which above all their doctrines of progress derived, has swept forward on an enormous front. The conquest of the air has made possible an intercourse and understanding between distant peoples such as our ancestors could not imagine—and it has been diverted to the vast destruction of men and cities. The invention of wireless telephony has opened a channel through which liberating truths might be proclaimed to all the listening earth—and every would-be despot has used it to suborn the blind masses into the worship of false gods. The medical art has performed miracles; the cures of immemorial pestilences have been found, infancy has been safeguarded and old age tended, so that the normal expectation of life has been extended by years—aside from the new and universal apprehension of sudden death."

To my mind it is vital that the two sides of scientific development are fully and clearly understood, not only by the research scientist, inventor, designer and the whole scientific team, but also by all laymen. The instrument of scientific knowledge in our hands is growing more powerful every day; indeed, it has reached a point when we can either set the world free from drudgery, fear, hunger and pestilence or obliterate life itself.

Progress in almost every form of human activity depends upon the continued efforts of scientists. The nation's wealth and prosperity are governed by the rapid application of science to its industries and commerce. The nation's workers depend upon science for the maintenance and improvement in their standards of health, housing and food. Finally, superiority or even our ability to survive in war is a direct measure of the excellence and capacity of the scientific team.

This team of research workers and engineers has a dual responsibility, one for its work and the other as informed citizens, and it can only fulfil its proper functions if its members have a sound general education as well as a thorough training in science. It is no less important that the people who control the scientific machine, both laymen and scientists, should have a proper understanding and appreciation of what science has grown into and its place among the great forces of the world.

It is clearly our duty as citizens to see that science is used for the benefit of mankind. For, of what use is science if man does not survive?

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

A HUNDRED YEARS OF METEOROLOGY

In his presidential address to Section A (Mathematics and Physics) Sir David Brunt outlines the development of meteorology during the past hundred years. Before dealing with his main theme, he points out that the Greek philosophers Aristotle and Theophrastus had developed meteorology in the fourth century B.C. so far that their ideas dominated the meteorological thought of Europe for nearly two thousand years, while Pindar set up a standard of forecasting which even to-day is difficult of attainment, except on rare occasions.

The re-awakening of independent thought took place about the time of the foundation of the Royal Society in 1660, and the influence of that Society remained very great up to the time when control of official meteorology in Great Britain passed into the hands of the Air Ministry in 1920.

Many workers with creative minds have, of course, been indispensable on the research side of meteorology, and the names which Sir David mentions include those of astronomers such as Halley and Laplace, and physicists such as Lavoisier, Wheatstone and Glazebrook. Of particular importance was Sir Napier Shaw, the more so because Shaw was instrumental in adding the names of those most prominent in Great Britain during the past sixty years, for example, W. H. Dines, C. J. P. Cave, E. Gold and G. I. Taylor. Shaw's services should be judged against the background of the Meteorological Office, to which he went as director in 1905. Shaw found a 'Slough of Despond', into which he contrived to instil some of his own enthusiasm. Shaw made the greatest written contribution to meteorology of the century when he published, in 1906, the memoir entitled "The Life History of Surface Air Currents", a work in which he was assisted by R. G. K. Lempfert. This anticipated the paper entitled "Life Cycle of Cyclones and the Polar Front Theory of Atmospheric Circulation", by J. Bjerknes and H. Solberg, which has laid the foundations of the method of forecasting weather which has been developed during and since the Second World War.

Turning then to the research work now being done in Great Britain as part of a revived scheme of international co-operation, Sir David points out that the problems receiving increased attention include: (a) the nature of the depression of middle latitudes; (b) effects of atmospheric radiation and absorption on the heat balance of the atmosphere; and (c) formation of cloud, rain, ice-crystals and snow. Items (b) and (c) have given the most positive results; as regards (a) we cannot predict where the next depression will form, or even explain the precise conditions which led to the formation of yesterday's depression. In the case of (b) the approximate balance of radiation and absorption in the atmosphere can now be evaluated by graphical methods due to Elsasser in the United States and Robinson in Britain. In the case of (c) we now nearly understand the condensation of ice, and also the artificial production of precipitation. Another new matter which is being investigated has come to the fore as a result of further advances in aircraft design, making flights possible at very high altitudes. These have revealed a new phenomenon called the 'jet stream'. This is a stream of air, at levels between 15,000 ft. and 40,000 ft., moving roughly eastwards at speeds of 130 knots or more, and traceable for great distances downwind, but sharply restricted vertically and transversely.

CHEMISTRY AT THE MID-CENTURY

In his presidential address to Section B (Chemistry), Sir Cyril Hinshelwood points out that a century ago there was a great wave of intellectual optimism, more recently succeeded by disillusion and pessimism from which recovery is to-day far from complete. At this moment there may be profit in taking stock of the realities of the situation and in examining against the general background some particular themes of interest to the science of chemistry.

The great chemical events of the past century have been the evolution of views about the basic substratum of things, the perfection of the arts of synthetic chemistry, and the growth of knowledge about the laws of energy and of the intimate mechanism of chemical changes. Now after a long and eventful approach the chemist stands face to face with the problem of life itself.

Early ideas about atoms and the manner of their union were naive. They have gradually become more sophisticated and more abstract, and now chemical valency must be interpreted in terms of electrons with properties quite unlike anything known to ordinary observation. Behind this there seems to lie some deep mystery relating the possibility of detection with the very existence of the entities postulated in physical theories, and in a glass darkly one seems to see here some connexion with the mind–matter problem itself. The present situation is unsatisfying to many; but it should not be concluded too readily that the limit of knowledge, or taking long views, even of the power of human understanding is yet reached.

Much of chemistry is of a more workaday character and unconcerned with these deep questions. Structural chemistry, now in the early stages of becoming a mathematical science, has not only revealed the underlying atomic patterns of things but also enabled the chemist to weave designs of his own choosing. The deeper understanding of mechanisms has not only led to understanding but also to control.

It has often been questioned whether the powers of chemistry are used for good or evil ends. To this an emphatic answer may be given: chemistry has in fact, conferred vastly more benefit than harm on mankind; and men of science are in no way responsible for the abuse of their discoveries by others. The desire to inhibit scientific discovery rests, moreover, upon an utter lack of faith in human destiny.

The detailed understanding of what happens in chemical changes has revealed a picture surpassing in wonder that conceived by the poetic imagination of Lucretius. It is now being extended to the events occurring in living cells. The selective influencing of cell processes opens the door to the great field of chemotherapy, though generations may pass before all the promise of this is fulfilled.

As the cell discloses its secrets there will emerge the possibility of deep-seated intervention of man into the fashioning of his own biological future, and those of little faith may raise more vigorous cries than ever.

Men of science at the mid-century are faced with difficult problems, both scientific and human. If in face of hopes and fears they seek a policy, they will do well simply to follow the advice of Candide: "Il faut cultiver son jardin". If they do this unconcernedly, their own garden will not fail to go on producing its fruits.

GEOLOGY AND MILITARY STRATEGY

The relation between geology and the movements of armies forms the theme of the presidential address to Section C (Geology) by Prof. W. B. R. King. Military operations in north-west Europe during the past two hundred and fifty years have illustrated as well as in any part of the world that the ability of a commander to move, feed and supply a large army at will is one of the prime necessities of a campaign, for this leads up to the successful deployment for the actual battle. The first of these necessities clearly depends on the general topographical lay-out of the country viewed in a broad way, while the details of the battle are often influenced by local geological controls.

Belgium, between the Meuse-Sambre and the rivers draining towards the Scheldt, has often been a 'corridor of invasion' between east and west, and many of the great battles from the time of Marlborough onwards have been for the control of this 'corridor'. The early battles of 1914 and 1940 were clearly influenced by the presence of this natural east–west throughway. The line taken up by the Allies in May 1940, based on the Scheldt estuary–River Dyle–Meuse valley above Namur, left only a short stretch of line without a natural defensive river position. That the Germans were able to turn this line by advancing through the difficult Ardennes country does not say that the line chosen was not a good one. Other defensive lines in northern France are essentially river lines, like that of the Somme running across what is, on the whole, open country.

When the general geological pattern of north-west Europe is considered, it is clear that the oft-repeated pattern of military operations can be co-ordinated with the physical geography of the area and this is clearly controlled by its geological history.

North-west Europe can be divided into five main areas: (1) the low-lying area of the north with wide sluggish rivers and large areas actually below sea-level; (2) the Chalk and high-standing Tertiary areas of Belgium and northern France with relatively few natural barriers; (3) the Palæozoic and igneous rocks of the Ardennes and surrounding Bunter Sandstone outcrops, a wooded area of high relief with deeply incised valleys; (4) the Paris Basin consisting of an outer zone of marked dip and scarp topography, a middle zone, that of the Chalk, an area of open country of well-drained flat surfaces and an inner zone of dissected wooded hills; (5) the Palæozoic area of Brittany and west Normandy with its strong east–west 'grain'.

Clearly, of these divisions, (2) and the centre zone of (4) are those most suited to easy movement of large armies, and historically it is in these areas that the main military operations have taken place. But besides the controls due to the solid geology, the area as a whole was in the periglacial zone during the Pleistocene Ice Age. This has had great influence on the physical features. The effect of a lowered sea-level due to abstraction of oceanic waters to form the ice-caps has been to cause a temporary rejuvenation of all the valley systems, particularly in their seaward portions. These overdeepened valleys were drowned on the recovery of sea-level to near its former position. This resulted in either large estuaries or, as occurred in most cases, valleys filled with recent unconsolidated sediments including peats. It is these deposits which make so many of the river lines such strong defensive positions, for the whole valley floor, not merely the river, is the barrier. The other important result of the periglacial climate is that it leads to the formation of vast sheets of loess spread over the country as a blanket. On the slopes this has been largely removed, but on the plateau areas it still exists. Its effects are numerous. On the loess soil the type of agriculture is plough lands with large open fields without hedges. The silty nature of the soil renders it firm and quick-drying during summer but highly treacherous in winter and spring. It is on such plateau lands during the summer months that airstrips for servicing fighter aircraft could be prepared with least work and where the open country was particularly well suited for rapidly moving armies.

The effects in the coastal regions of movements of the strand line were important. Along all the Channel coasts it was known that peats and clays of the 'Submerged Forest' existed in patches. The location of patches of these under the sands of the Normandy beaches necessitated extremely intensive study, for unless covered by a sufficient thickness of sand, vehicles were liable to become bogged. The work done by Prof. F. W. Shotton and others on this problem was well justified by the results.

It is seen, therefore, that the solid geology of the area controls the broader problems of strategy, while the features resulting from the periglacial position during the Ice Age has had two effects which have been of the greatest importance in controlling details. These are the infilling of the overdeepened valleys with unconsolidated alluvium, rendering them effective barriers, and the presence of the loess-covered plateaux which form large areas suitable for 'open' warfare and give rise to numerous tracts which can be turned rapidly into temporary airstrips for the landing and servicing of fighter aircraft, a feature of the greatest importance for modern armies.

ORGANIC DESIGN

In his presidential address to Section D (Zoology), Dr. C. F. A. Pantin remarks that by the beginning of the nineteenth century two principles had emerged from the study of comparative anatomy: first, that structures are adapted to the function which they serve; secondly, that some plan underlies the architecture of whole groups of animals. Purposive adaptation was used as an argument for Divine design. So also was the existence of an underlying anatomical plan. This plan showed two features. First, animals exhibited grades of organization which we term 'higher' and 'lower'. This was partly the old anthropomorphic over-simplification that placed man at the head of a *Scala Naturæ*. The error still persists because it contains an element of truth. 'Higher' animals show functional differentiation which leads to increased independence of the environment. The price of this independence is centralized control, particularly by a brain.

The second feature is that animal organization is found to be based on one or other of a series of architectural types, such as the vertebrate, the molluscan and so on. One hundred years ago, Richard Owen gave precise definition to this idea in his conception of the archetype, which he considered as the expression of an underlying abstract plan—in much the same way as to-day we may consider the groups of the elements of the Periodic Table give expression to such a plan.

The "Origin of Species" gave a totally new interpretation of these things. The type and its structural homologies were consequences of evolution from a common ancestor. Purposive adaptation was the negative image of natural selection.

By 1918 abstract comparative anatomy, even in evolutionary guise, had lost much of its power to inspire research. Many new lines of work opened, particularly in the physiology of animals and their tissues. Almost all these lines have led back to morphology, though from a very different point of view from that of the older comparative anatomists. New relationships emerged at the molecular level of structure. Biochemical similarities appeared between organisms which were utterly sundered in their evolution, as in the carbohydrate metabolism of fermenting yeast and of contracting muscle in vertebrates. Such similarities arise independently because the materials available for the construction of organisms are of few kinds and of unique properties. Consequently the same materials, and these alone, are available again and again for the construction of functional systems independently in different sorts of organism.

Once these limitations are introduced at the molecular level, they affect all higher levels of structure. One of the most remarkable features of comparative physiology is the repeated and independent utilization of the same kind of machinery for muscular movement in quite different animals.

As in the structures erected by engineers, so in the organism, there are three factors governing design: first, any functional problem can only be solved in a limited number of ways; secondly, for any solution only materials of limited kinds and properties are available; thirdly, the engineer selects a solution which he can execute with the materials available. In the same way we may say of living organisms that natural selection gives reality to one or other of a series of possible structural solutions limited by the properties of matter and energy.

As a result of these limitations, we repeatedly find the same structural solution of a functional problem achieved by quite unrelated organisms. The most striking example of this is the independent development of similar nervous machines by which organisms execute their behaviour.

THE CENTENARY OF SECTION E (GEOGRAPHY)

The year 1951 marks the centenary of Section E (Geography) in the British Association, and its president, Dr. O. J. R. Howarth, surveys its history and achievements. The subject was previously subordinated to geology, and for some years was confined to physical geography. The establishment of the new section, in which ethnography was at first included, was due to Sir Roderick Murchison. He helped to found the British Association and also the Royal Geographical Society: he was to become a general secretary and afterwards president of the Association, and he maintained an intimate interest in the new Section, assuming its annual presidency no less than seven times. His first conception of its main function was that it should deal with travel, and should attract the interest of lay members of the Association by bringing before them eminent explorers in person: "A noble procession of explorers passed across the stage of the Section"—Burton and Speke, Livingstone and Stanley, Wallace, Sturt, Palgrave, Scoresby, Ommaney, and many more.

The standing of geography as a true science was viewed with doubt by scientific purists. As a result, geographers and others disputed the question 'What is geography ?' at greater length than was justified. The Section never actually debated this question; but a succession of addresses and papers attempted to answer it in various terms: those who in the earlier years of the Section saw the answer most clearly were Strachey and Clements Markham. The present address tries to show that "what Geography has achieved in the century we are reviewing, and what Section E has very effectively aided in achieving, is to demonstrate an outlook wider in horizon than those of the other departments of science with which it is associated, and to help to bring them into a harmonious focus".

By means of examples from the sectional transactions, the developments in British geography in various directions are traced—survey and cartography, geomorphology and the introduction of natural regions by Herbertson, human geography, and geography as an educational subject. Occasion is taken to refer to the work of many of the leaders in the development of geography—Keltie, Mackinder, Mill, Chisholm, Dickson, Geddes, Roxby and others. Dr. Howarth had personal contacts with some of these; but has not ventured into the fields of the work of those who have come after them and still are active. He suggests, however, "that in the century which is past British geographers have enunciated their principles and begun to apply them; have indeed applied them so far that the time is ripe to express them, not only in terms of individual researches (as is done) but in terms of a new geographical encyclopædia"—a suggestion easy to make, but less easily carried out "against the barrier of present-day costs".

Following upon the remarks on geography in education, it is suggested that to foster the instinct for admiring and preserving natural beauty is a function of geographical teaching alongside the organizations and individual activities which work to that end. "In this connexion we owe constant attention to the literary side of our subject, for much can be achieved by well chosen words, whether with or without opportunity for visual guidance." Geographical works are not the only sources of inspiration: by way of example, an illustration is quoted from the work of Robert Louis Stevenson.

There is an appendix to the printed version of the address, in which very brief biographical notes are provided of some seventy geographers and supporters of geography mentioned in the text.

NATURE OF PROFIT

To the questions what profit is and by what causes it is shaped and determined, economic science has not yet supplied answers which command general agreement. In his presidential address to Section F (Economics), Prof. R. G. Hawtrey points out that the classical economists, Adam Smith, Ricardo and Mill, recognized that profit must be distinguished from interest. Profit is the remuneration of the active head of an enterprise, whereas interest is paid, for the use of money, to a capitalist who takes no active part. The profit remaining after providing for interest is, therefore, remuneration for services rendered. But it differs from a wage or salary in that it is proportional to the magnitude of the trader's business, so that an expansion of the business may mean an indefinite multiplication of his income.

Marx accepted the classical view of profit and went so far as to describe the profit-making capitalist as a 'wage labourer', but with the qualification that the wages which he claims "do not depend on the degree of his exertions".

Marshall's treatment of profit had an apologetic flavour. He approached the subject from the point of view of a representative firm, one not exceptional either in efficiency, size or luck. The profit of such a firm would not be more than fair remuneration for services rendered. The rate of profit would vary widely. But an essential part of the cost of using capital is risk of loss, and uncertainty means inequality. However, it was the concentration of industry in big units that Marx had attacked, and Marshall's representative firm did not pretend to offer a defence against that attack.

Marx had in mind the concentration of industry that mechanization makes possible. But there had been from time immemorial another kind of concentration, that of the large-scale merchant's business.

The purpose of production is to meet needs, and the function of the merchant is to marry the product to the needs which it is to meet. It is a skilled service remunerated by the difference between buying price and selling price—in fact, by profit; and the merchant's income has the special characteristic of profit, that it can be multiplied in proportion to his transactions. The merchant's profit is the remuneration of selling power. It is paid for his skill in selecting goods to suit the needs of consumers and users. The industrialist is no less a seller than the merchant, and his profit is likewise the remuneration of selling power. He has also other responsibilities, but can delegate them to a salaried staff. The responsibility for selling attaches inseparably to the *owner* of the product to be sold.

How then are profits determined under competitive conditions ? The profit margin in any trade must be such as to secure a reasonable income to a newcomer. It will be regulated by the *magnitude* of the business that the newcomer with his command of capital and business connexion can expect. Even the passive shareholder, being part-owner of the product to be sold, gets more than bare interest on his money. That is his reward for making a wise selection among profit-makers to whom to tie his fortune.

Concentration of selling-power is more productive of near monopolies than concentration of industry, but is not always so serious an abuse as appears. The big concern can afford to be content with a narrower profit margin than the small; and the accusation is usually not that its prices are extortionate, but that it treats its competitors harshly.

Profit-making is attacked nowadays from within the capitalist system. The advance of democracy has given an equalitarian bias to taxation. Here the danger is a destruction of saving at its most fruitful source.

2,000 YEARS OF ENGINEERING

SIR CLAUDE GIBB's presidential address to Section G (Engineering) traces the development of engineering from prehistoric times up to the present day and concludes with a prediction of future developments.

Engineering was born of the requirements of man, who, during his gradual development from a barbaric savage, fashioned tools and weapons to obtain food and to protect himself from the beasts of the forests. With the growth of civilization, man required irrigation schemes, canals, docks and harbours, good roads, palaces and temples, and the engineer had to use much ingenuity to provide these wants.

Ancient Greece furnished us with a number of eminent engineers, including Alexandrinus, Hero of Alexandria and Archimedes, and their work formed the basis for our knowledge of many subjects. The Romans also did much to further the art of engineering, the building of roads being one of their greatest achievements.

As the mining industry in Great Britain developed, some form of pumping engine and raising gear became necessary. Engineers turned their attention to this problem, which resulted in the introduction of the reciprocating engine. Engines of this type were also used for driving the paddle-wheels of sea-going vessels, and this eventually led to the introduction of screw propulsion, and the general use of steam engines at sea.

Some cheap and quick method of transporting coal from inland collieries to the river shipping points led to the construction of steam locomotives for coal haulage, and later the steam locomotive was adapted to passenger-train service.

Tribute is paid to the work of the engineers and physicists who gave us the laws of thermodynamics. Watt, Count Rumford, Carnot, Joule, Sir William Thomson, Rankine and Clausius all played their part, and it was the work of these physicists that made possible the rapid advances in steam engineering.

Due to the activities of many inventors, the beginning of the nineteenth century was an important period in the history of electricity. Electric generators came into being, and the electric telegraph services were introduced. Later the trans-Atlantic telegraph services, the telephone and electric lighting all made their appearance. Sir Joseph Wilson Swan and T. A. Edison gave us the incandescent electric light; then came the public lighting companies, followed by Ferranti and his work at the Deptford Power Station.

Equally important developments took place in the prime movers for driving the electric generators. Starting with the semi-portable agricultural type of engine, the Peter Brotherhood high-speed direct-coupled engine was introduced, followed by the Parsons epicycloidal engine, the Willans engine, the Bellis engine and finally, in 1884, the Parsons turbine. After the success of the turbine for the driving of electric generators, Parsons attacked the problem of adapting the turbine to marine propulsion and, after many initial disappointments, was equally successful. It was Sir Charles Parsons's work which made possible the large turbo-alternators used in central power stations and the large liners, cargo vessels and naval ships of to-day.

The advent of coal gas at the beginning of the nineteenth century saw the introduction of the gas engine and its development by Otto and Clerk. While these developments were taking place, the discovery of petroleum led to the use of oil instead of gas as fuel, the earliest oil engine to achieve success being the Priestman engine introduced in 1885. The Daimler engine followed; this was the beginning of the modern petrol engine, and its dramatic use for nearly all modern self-propelled vehicles.

The success of the petrol engine on land was followed by its use in the air. During the First World War, rapid advances were made in the design of aeroplanes, and in 1919 the Atlantic was crossed by aeroplane. Research work undertaken by Sir Frank Whittle gave us the jet-propelled aeroplane, and the development work during the Second World War produced the large aircraft used for the present-day long-distance passenger services.

Although efforts had been made at the beginning of the century to introduce gas turbines, it was not until about 1935 that serious attention was again given to the subject. While the War slowed up these developments, work still proceeded. On the Continent, gas turbines for outputs up to 27,000 kW. are in operation and in Great Britain machines of 10,000 kW. and 15,000 kW. are nearing completion.

In recent years considerable attention has been given to the work of the scientific men investigating nuclear energy, and to the possibilities of adapting this source of energy to commercial work. The first atomic pile was put into operation in the United States in 1942, and during the War considerable progress was made. Since 1945 atomic energy establishments have been put into operation in Great Britain at Harwell and at Sellafield.

In predicting the developments of the future, Sir Claude considers large-scale railway electrification is possible, following the production of electrical energy from the use of fissile material. To justify the high initial cost of an atomic energy plant, the production of electrical energy by fission must be carried out on a large scale, and so electrification of railways using electrical energy on a large scale will automatically result. He considers the jet or gas turbine cum jet will be used to the exclusion of all other means of propulsion for all types of aircraft. This type of prime mover meets the requirements so admirably that it is difficult to see how any other form of prime mover can compete. On land, the gas turbine will be used possibly to supplant the Diesel engine; but for very large powers the steam turbine will still be used. He sees no difficulty in making gas turbine units of 100 h.p. which could be fitted to motor-cars within the space now occupied by petrol or Diesel engines, the only problems requiring solution being a low cost and highly efficient regenerative heat exchanger.

Large-scale use of electricity for pump-produced rain and for soil heating will help to solve our ever-growing food shortages, and supersonic frequency electronically produced vibrations will become an everyday thing in our industrial, domestic and medical life.

EARLY CELTIC METAL-WORK IN BRITAIN

THE presidential address to Section H (Anthropology), by Sir Cyril Fox, opens with a reference to the great collection of Celtic metal-work from Llyn Cerrig, in Anglesey, of the period 150 B.C.–A.D. 50, spread out on a workroom bench in a museum in war-time. For a study of parallels to individual pieces, museum collections were not then available; Sir Cyril was dependent on the literature, and found it very inadequate. That sense of inadequacy was the reason for choosing the subject for his address.

The character of this Celtic metal-work is discussed, specially fine examples referred to, and the absence of good monographs deplored. Some large hoards discovered fifty to a hundred years ago, it is pointed out, are not yet completely published or assessed. Reasons for the lack of enterprise thus indicated are suggested, and remedies for the lack of interest in this first flowering of British art outlined.

After referring to Dr. Jacobsthal's important researches, which promise, in time, a comprehensive survey, Sir Cyril outlines his own investigations: in brief, he has been concerned with the life-history of a particular artistic idea—or the art-history of a particular motif or group of motifs—in the last hundred and fifty years of Celtic freedom in southern Britain. The antecedents of the Llyn Cerrig plaque, the piece first chosen for investigation, its development as a three-dimensional work and transformation into a two-dimensional pattern, and the variations that flowed from it, are aspects that find a place in the series of published papers on the subject.

None of the more elaborate of the British Celtic patterns had hitherto been intensively studied; it is now seen that some at least are not so individual as to be at this distance of time inexplicable, but form closely related groups which can be placed in evolutionary series. The dependence of the Celtic craftsman on traditional patterns and the slow *tempo* of change despite his originality of mind and advanced technique are factors which make such elucidations possible. The backs of many Celtic mirrors, for example, are decorated, and this decoration is regarded as springing from one source, namely, the triskele, present on the Llyn Cerrig plaque. It culminates in the well-recognized high achievement of the Desborough mirror, wherein the graceful design of the mirror-back is matched by the beauty of form of the handle, both being fused, by art and artifice, into a unified structure.

The fold-over symmetry of many mirror designs, dating as these do in the period A.D. 1–50, has been recognized as due to the influence of Roman art; an attempt is now made to tie the achievement more closely to that source, since in its barbaric fashion it reflects something of the delicacy of perception and execution, the serenity of mood, which characterizes that art in the Augustan age.

It is held to be probable that the popularity of the triskelar pattern in British art was due to its magical significance, and a neglected stone aniconic object carved with triskeles, found near Gloucester fifteen years ago, is regarded as important in this connexion.

The difficulty met with by students in working out the history of early Celtic patterns, and the regional distributions of such—which require us to neglect no decorated piece of Celtic metal-work of the period in the country—arises from the lack of any organized centre for such study. Each individual repeats the laborious task of his predecessors: search through the scattered literature, and visits to museums to see described but unillustrated examples in the hope that they may be relevant to his needs. The creation of a card index of early Celtic metal-work in Britain, then, is urged, accessible to all accredited workers, and preferably linked to some institution, so that when completed to date, it will be kept up to date. It is hoped that an English school of research on early Celtic art may grow up in connexion with the development of such an index; it is gratifying to record that such a school for Scottish Celtic art may be held to be already in being in Edinburgh.

PHYSIOLOGY OF THE CAPILLARIES

THE presidential address to Section I (Physiology), by Prof. H. P. Gilding, forms the preface to a whole day's discussion on "Body Water". A brief outline of capillary structure serves as introduction. The complex patterns of capillary networks differ from organ to organ. That seen in simple structures such as the mesentery, so widely portrayed, can be very misleading if this picture is taken as a model for the rest of the body. In most structures the arterioles and venules run together until their final ramification, when they separate; this is best seen in skeletal muscle. Here the arterioles and venules lie transverse to the longitudinal axis of the muscle fibres, and ultimately the arteriole separates from the venule in such a manner that the latter is draining blood from arterioles on either side of it, with longitudinal capillaries of between 0·43 and 1·35 mm. in length joining them. Thus, between two transverse arterioles or venules a distance of more than 2 mm. is commonly found.

These facts were sufficiently well known a hundred years ago to be described and depicted in standard text-books of that time; it is not a little surprising that factual knowledge so important in consideration of capillary function should have been neglected and forgotten. It will be obvious that in skeletal muscle the lengths of the longitudinal capillaries are several hundred times their breadth. If we consider the maintenance of muscle fibres, another significant point emerges; along a given muscle fibre, alternating areas approximately 2 mm. apart are richly supplied by arterial blood, while the portion of fibre between is served by increasingly venous blood. These facts must be borne in mind when dealing with capillary tissue exchanges.

The evidence for the view that there is a gradient of capillary permeability is briefly discussed and reasons advanced for the necessity of such a gradient.

Consideration of known capillary and venous pressures throws doubt on the popular view of arteriolar-capillary filtration and venular-capillary absorption. Venous pressures measured in the dorsum of the human foot in quiet standing give readings of about 90 mm. mercury; this high pressure must be reflected in the capillaries, and therefore prevailing hydrostatic pressures in the foot during standing are such that filtration should, theoretically, continuously predominate and result in œdema. Common experience shows that this is not so. Similar considerations hold for the condition of affairs in the abdominal cavity. The portal capillary pressures in the supine animal are known to be higher than elsewhere, and furthermore these vessels are more permeable to protein. In the erect human being, gravity will increase the venous and capillary pressures over and above that in the horizontal position. We can calculate, therefore, that the prevailing colloid osmotic pressures are differentially too low physically to re-absorb the fluid, which is usually assumed to be filtered at the arteriolar end of the vessels.

The concept of capillary permeability being dependent on pores of varying sizes is discussed and repudiated.

Modern work using radioactive isotopes to measure capillary permeability is reviewed and reasons advanced for considering endothelial permeability as being comparable to cell membranes in general.

PSYCHOLOGY AND THE LAITY

THE century between the two great Exhibitions has seen the emergence not only of the science but also of the profession of psychology, and this is the keynote of the presidential address of Prof. C. A. Mace to Section J (Psychology). A 'ministry of the mind' has been created which is in many respects parallel and co-ordinate with the 'ministry of the soul' and the 'ministry of the body'. The acceptance of responsibilities by the psychologist in education, in industry and in the personal lives of men might seem to constitute a challenge to the vested interests of sagacity and experience, and to threaten yet further restrictions on individual liberty.

The surest defence against the danger, if danger there be, lies in the education of an understanding but critical laity. It is, indeed, upon the existence of such a laity that the success of the new profession must depend. The psychologist works indirectly, since when principles of psychology need to be applied it is almost always the layman who has to apply them. If reassurance be needed, it may be found in some measure in the history of the science in Great Britain. It has its roots in British natural history. The story of its growth could almost be told through the lives of three generations of the Darwin family. Erasmus Darwin was the first of the moderns to conceive the science of psychology as an integral part of biology. His grandson Charles applied the methods of the experimental naturalist to psychological problems. The other distinguished grandson of Erasmus, Francis Galton, could fairly be described as the founder of modern experimental psychology, since in his work, more than elsewhere, may be found the beginnings of so many of the most vital contemporary lines of research. He was the first of the experimental human naturalists—a psychologist of the field as well as of the laboratory. Among our near contemporaries, Charles Myers belongs to the same intellectual lineage.

In this tradition two features are outstanding. Erasmus Darwin, Galton and Myers did much to bridge the chasms that divide the arts, the sciences and the technologies. All were men of science who worked in close association with the scientific laity. The future of psychology, perhaps more than that of any other science, depends upon the preservation of this British tradition—since it is both *by* the layman and *to* the layman that psychology is in the main applied.

There is, accordingly, a distinctive approach in psychological research. The need for 'multidisciplined operational research'—the combined attempt of many specialists to solve practical problems in a scientific way—is now widely recognized. But in psychological research the layman who possesses special and relevant experience is an essential member of the research team. In many such cases this relevant experience may be in the field of the arts or the technologies. This approach is important in so many of the problems of technological education. It is important, too, for the solution of the problems of 'consumer assimilation' of the results of scientific research in every field. The piling up of the unapplied findings of scientific research is due in the main to the lack of machinery for co-operation between those who make discoveries and those who can apply them. The problem is especially acute in the field of the human and social sciences. We need a new conception of the function of a psychological laboratory or institute for psychological research. Such an institute needs to combine the features of a laboratory with those of a field station—to which intelligent amateurs will come, not for ready-made solutions to their problems, but for working hypotheses to test in their lives and daily work.

The need for co-operation between professionals and the laity gives additional significance to the current demands that scientific findings should be expressed in the common language of all educated men. The psychologist most of all needs to be bilingual—using whatever technical terminology he prefers in his purely professional circles, but speaking also in the language of the common educated man. The demand is not exacting; because although psychology is a very difficult subject, it has nothing in it which cannot be expressed in language which an intelligent fifth-form schoolboy can readily understand. Psychologists do not write cryptic prescriptions. They have no secret remedies. All they know they can and must tell. The function of the professional psychologist is not to cultivate a mystery but to communicate understanding, first of all to parents, then to teachers, and then to all who in any way are concerned with the supervision and management of men. So to report the facts of science is in the British tradition. It is in virtue of this tradition that the British Association is a British association—an association of professionals and laymen.

MYCOLOGY OVER A CENTURY

A REVIEW of the advance of mycology over the past hundred years, which constitutes Prof. W. Brown's presidential address to Section K (Botany), must be to all intents and purposes a review of the whole subject as a branch of science. Taxonomic mycology had taken shape in the early part of the nineteenth century, at least as regards the larger fungi; but any scientific treatment of the much larger number of microfungi (including bacteria) was impossible so long as it was held that such small organisms arose by spontaneous generation. A little less than a hundred years ago Pasteur established the biological theory of fermentation and disease, and the parallel work of de Bary and the Tulasne brothers laid the foundations of modern mycology.

The earliest researches took the form of mapping out the life-cycles of fungi, with the ultimate object of fitting the group into the scheme of Hofmeister, which had already been shown to apply to all groups of plants from the Bryophytes upwards. The task was difficult, on account of the reduction and even elimination of sex organs in the higher members of the fungal series, and it was only towards the beginning of the twentieth century that advances in cytological technique made the complete elucidation of certain life-cycles possible. These studies form the basis of the modern classification of fungi and of views regarding their evolutionary descent.

Much work has arisen from the discovery of heterothallism in fungi. Many of them exist in two forms (which may roughly be called male and female) and in general the life-cycle cannot be completed unless these two forms come together with resultant nuclear fusion. It has been possible, on this account, to adapt the Mendelian method of study to fungi (including yeasts), so that there is now a flourishing line of fungal genetics. Fungal species in general consist of a cluster of strains, and it is possible to produce new ones by suitable mating. In this way new strains with enhanced value for industrial purposes—for example, yeasts for brewing, strains of *Penicillium notatum* for penicillin manufacture—have been developed.

The smaller fungi, especially moulds and yeasts, offer many conveniences for research on cell metabolism and on respiration in particular. The process of alcoholic fermentation by yeast has the special interest that it is closely related to anaerobic respiration, which is known to precede the normal aerobic respiration characteristic of all animals and most plants. Hence the wide biological significance of yeast biochemistry. Biochemical studies of fungi and bacteria, important from the fundamental point of view apart from their industrial interest (as in the preparation of citric acid, acetone, glycerol, certain vitamins, etc.) have become very active in recent years in connexion with the search for antibiotic substances, such as penicillin and streptomycin.

Two lines of physiological research on fungi have interesting parallels elsewhere. One of these concerns the response of fungi to minimal traces of certain metallic elements (zinc, copper, manganese and others), a response which is comparable to that of many higher plants; the other concerns the requirement by fungi of small quantities of special organic substances (biotin, aneurin, etc.), some of which are related to vitamin B. This behaviour is comparable with the dependence of animals on a vitamin-containing diet.

The interrelations of fungi and other plants are many and varied. Mutualistic effects between micro-organisms largely determine their localization in Nature and the frequency of their occurrence, and have been much studied in relation to the biology of soils. Beneficial effects (symbiosis) between micro-organisms and higher plants are shown in the fungus roots (mycorrhiza) of many plants such as grow in soils of high humus content (heath plants, orchids, many forest trees). Nodulation of the roots of leguminous plants is another example, and this is of the greatest importance in connexion with soil fertility. Harmful effects, which are not always sharply distinguished from symbiosis, are seen in the wide range of plant diseases caused by fungi. The development of plant pathological research on a nation-wide scale is one of the major mycological advances of the period under review.

MID-CENTURY—RETROSPECT AND PROSPECT IN EDUCATION

IN his presidential address to Section L (Education), Sir Hector Hetherington points out that the development of public education in Great Britain over the past hundred years reflects the same impulses or ideas which have expressed themselves in the changing pattern of social, political and economic institutions and policies. The two dominating elements in that movement have been the coming to full maturity of the natural and applied sciences, and of the technological civilization founded thereon: and on the other hand, the wider operation of a principle best described by Dr. Gilbert Murray's word 'liberality'. The essential social history of the period is that of the effort to overcome the class divisions produced by the first impact of the Industrial Revolution, to diminish differences in economic status and in political responsibility, and therefore also in educational and social opportunity. The process has been gradual, undoctrinaire, experimental, controversial as to method but not as to broad objectives, and in the course of a hundred years has been carried a very long way.

The corresponding development in public education was influenced no doubt by the need of an expanding industry for more skilful, and therefore for better educated, workers, just as the movement fifty years ago towards wider secondary and technical education was influenced by the technical outpacing of Great Britain by Germany and the United States. But the main impulse undoubtedly was the force of the moral demand, and the main struggle was over the assertion of the State's direct responsibility. The State's concern for elementary education had been asserted in 1833. The State's full responsibility for it was not established until 1870. Its legalized and explicit participation in secondary education was not established until 1902, and its responsibility for the provision of a full educational experience—'compulsory secondary education for all'—dates only from 1944.

Just as the century's changes in economic and political institutions and practice have left some obstinate problems still unsolved, so also in the field of education. Great progress has been made, beyond doubt; but it has been progress in the creation of opportunity rather than in its assured and effective use. Large material problems remain—a shortage of teachers and a scarcity of well-equipped schools. Perhaps even more urgent is the definition of the use to be made, especially for the non-academic pupil, of the longer school-life. At that stage vocational and technical education is of high personal and national importance. But the essence of the matter is to discover how best to use these instruments as an introduction to a free and intelligent participation in the interests and responsibilities of a civilized society. To that end, the linkage with voluntary adult education is of great significance.

The favourable elements in the situation are the gradual emergence not of a single organic structure of national education, but of closer and more co-operative relations between many different elements, old and new, government and voluntary, formal and informal, and the reinforcement of the State provision by youth services of all kinds. But it is important to recognize that under modern technological conditions there are strong influences making for mass emotion and mass action, and that the educational system has it in trust to preserve the values of a free society.

EXPERIMENTAL AGRICULTURE

DR. E. M. CROWTHER, president of Section M (Agriculture), points out that the first critica review of the difficulties in obtaining reliable in formation in experimental agriculture was publishe a century ago by J. F. W. Johnston, who held the post of chemist to the Agricultural Chemistry Association of Scotland. Johnston realized the

Physics Dept. 92, Upper Circular Rd, Calcutta

necessity for having at least two plots for each treatment and the advantages of comparing manures "both singly and in combination". Field experiments with single plots per treatment were still being made in Britain until well on into the present century, though replicated plots in systematic arrangements were employed on the Continent from 1880 onwards. The whole subject of agricultural experimentation was transformed around 1925 by R. A. Fisher, who established the necessity for a measure of randomization in assigning treatments to plots and showed how the precision of the experimental results could be estimated. The factorial design of experiment, developed by R. A. Fisher and F. Yates, provided one of the most generally useful patterns of field experiment. There is an urgent need for series of these experiments for settling practical problems and providing basic facts for laboratory investigations.

Scientific concepts are often used somewhat loosely in interpreting agricultural observations, although no means have yet been found for testing their relevance. The contrast between the deductive and the inductive approaches to soil fertility problems was well illustrated in the famous controversy a century ago between Liebig and Lawes. The difficulty of relating laboratory research to practical agriculture still remains. Many laboratory techniques are too elaborate to be applied to the large numbers of samples needed in modern field experiments and soil surveys. Agricultural research has its own version of a principle of indeterminacy—the more exacting the technique, the less adequate the conditions under which it can be employed. Sometimes the difficulty arises in the opposite direction. Physical and biochemical investigations on soil structure are held up through lack of soil samples in which contrasted structures have been produced under experimental control in rotation experiments with different kinds and length of ley. So far, the field experiments required have proved too difficult.

It is essential that field experimental work should not be wasted on matters of purely local and temporary concern, but should be planned to make the fullest use of, and to provide the best raw material for investigations in, other branches of agricultural science.

The problem of balancing the various lines of approach may be simplified, in research and in teaching, if it is realized that agricultural science does not seek to establish general principles from which agricultural practices may be deduced, but has a more modest aim. Agricultural science may be regarded as a search for patterns of performance to be fitted to suitable landscapes. Its starting-point is current practice in the region concerned or in a similar one. The features of many environments and the effects of most agricultural operations can be classified sufficiently well for forecasting the effects of moderate changes in practice, but it is unwise to make drastic innovations without pilot schemes and detailed experiments.

The final paragraph from the introduction to Johnston's "Experimental Agriculture", published in 1849, is still relevant to-day. "It is only by means of conjoined experiments in the field, the feeding-house and the laboratory—all made with equal care, conscientiousness and precision—that scientific agriculture can hereafter be with certainty advanced. If we have been long in getting upon the right road, we ought to advance the more heartily now we have found it."

THE SCOTTISH SCENE

IN his presidential address to the Conference of Delegates of Corresponding Societies, Dr. Douglas A. Allan points out that the systematic survey of any scene should begin with its rock foundations. The Scottish scene is composed of the Pre-Cambrian area of the Highlands, the older Palæozoics of the Southern Uplands, the Old Red Sandstone and Carboniferous of the Midland Valley, and the Tertiary volcanics of the Hebrides. These determine the distribution of basic economic minerals, and to a large extent the pattern of the scenery; but the final touches are due to the recent glaciation, from which the modern river-drainage system and the spread of soil layers derived. With amelioration of climate, belts of vegetation advanced across the country, to be followed by a variety of animals and, finally, man. Man the food-gatherer was succeeded by man the settler, with his specialists of priests and warriors. All can be traced through Scotland by arrowheads, beakers, brochs, vitrified forts, and a multitude of remains.

Roman police occupation south of the Forth and Clyde for roughly a hundred years is marked by roads and forts. Christianity came north-east from Ireland and north-west from the Continent, as evidenced by ruined chapels and treasured shrines, while the Vikings, at first pagan and later Christian, for fully four hundred years raided and settled on coasts and islands, leaving customs and language as well as boats and buildings as their contribution to the making of the land and its people. The Wars of Independence barred the way to English culture but developed links with the Baltic, the Low Countries and France, all of which left their mark on Scottish arts and crafts, industry and learning. The four Scottish Universities came into being between 1412 and 1582. The union of the Crowns in 1603 and of the Parliaments in 1707 led to peaceful development, save for the Wars of the Church and the two Jacobite risings. Then came the Industrial Revolution, and the exploitation of the mineral wealth of the Midland Valley, the tough man-power bred of a warlike tradition, and an ingenuity stimulated by a wealth of contacts overseas.

The characteristic devotion to learning, once peace and a modest economic stability were secured, was reflected in schools and colleges, scientific and learned societies, and private and corporate collecting of antiquarian and natural history specimens. There are some seventy museums stretching from Stranraer to the Shetlands, each of which in some degree houses and explains examples of the geology, botany, zoology and human history of their districts; and eight regimental ones telling their special story, inevitably extending far overseas. The societies and museums of Scotland thus collect and preserve not only material individually interesting and important, but also as a team present for to-day and to-morrow a facsimile and a synthesis of the land, its inhabitants, and its history. To their aid have come such official bodies as the Ministry of Works with its Inspectorate of Ancient Monuments, and such unofficial ones as the National Trust for Scotland for Places of Historic Interest or Natural Beauty, both of which, in one form or another, have instituted site museums in special areas. In 1947 it was recommended that a National Parks Commission for Scotland be established, with the aim of preserving stretches of country carefully chosen as typical examples of wild scenery.

The Forestry Commission, to which has been entrusted the task of restocking vast areas despoiled in the course of the two World Wars, has extended its service by providing national forest parks in those high-level parts of its estates where planting would be unprofitable. The preservation of scenes and woodlands calls for similar action to save their wild life, that is to say, precariously balanced assemblages of plants and animals. To attempt this there has come on the Scottish scene the new Nature Conservancy; but to achieve it will call for prolonged and conscientious observing, collecting and recording by a field force of amateurs. This is a clear call to action which the Corresponding Societies must not ignore.

NEWS and VIEWS

Genetics at Adelaide: Dr. D. G. Catcheside, F.R.S.

The Executive Committee of the Commonwealth Scientific and Industrial Research Organization has recently made arrangements for the strengthening of animal genetics in the School of Zoology of the University of Sydney, and has guaranteed to the University of Adelaide, for the first ten years, a chair of genetics which will be held at the Waite Agricultural Research Institute of that University, where a programme of plant breeding has been in existence for some years, and where a postgraduate school in plant genetics has been recently developing. Dr. D. G. Catcheside, reader in plant cytogenetics in the University of Cambridge, has accepted the new chair and will take up his duties in 1952. Dr. Catcheside graduated at King's College, London, in 1928 under Prof. R. Ruggles Gates. His first post was as assistant in botany in the University of Glasgow. He returned to King's College as assistant lecturer in 1931 and later became lecturer. R. P. Gregory had started the teaching of cytology and genetics at Cambridge before the First World War. After Gregory's death at the end of 1918, Prof. F. T. Brooks, then lecturer in mycology, carried on the work until Dr. Catcheside arrived to relieve him. Under Dr. Catcheside's leadership the subject rapidly developed at Cambridge and became a prominent part in the training of students in botany for the Natural Sciences Tripos. Dr. Catcheside's growing reputation attracted an increasing number of research students to Cambridge. In 1944 he was elected to a fellowship at Trinity College, Cambridge, and in 1950 he was made reader in plant cytogenetics. In 1951 he was elected to fellowship of the Royal Society. His interests are wide and include the cytology and genetics of *Oenothera*, the cytological and genetical effects of ionizing radiation, and the biochemical genetics of *Neurospora*. His work is well known in the United States, where he spent the year 1936–37 as a Rockefeller Foundation Fellow at the California Institute of Technology under Prof. T. H. Morgan and his sabbatical leave at Stanford University in 1947. Dr. Catcheside's promotion to the chair at Adelaide will be a serious loss to the Botany School at Cambridge.

Astronomy in the University of Manchester: Prof. Z. Kopal

Dr. Zdeněk Kopal has been appointed to a newly created chair of astronomy in the University of Manchester. Dr. Kopal was born in Czechoslovakia in 1914 and graduated as a doctor of science of the Charles University, Prague, in June 1937. He held the Ernest Denis Fellowship of the Czechoslovak Government during January–June 1938 at Cambridge, working under the late Sir Arthur Eddington. From September 1938 he held a research fellowship at the Harvard College Observatory, Cambridge, Massachusetts, becoming a research associate in Harvard University in 1940. During August 1942–June 1946 Dr. Kopal was on leave of absence, undertaking war work at the Massachusetts Institute of Technology, where he became in 1946 a research associate; in 1947 an associate professor of applied mathematics; and in July 1949 head of the Institute's Computation Laboratory. Since 1949 he has also been an honorary lecturer at Harvard University. The majority of the large number of scientific papers published by Dr. Kopal have dealt with the theory and observation of variable stars. His monograph, "An Introduction to the Study of Eclipsing Variables", is the standard work on the subject. He has also studied the oscillations of various stellar models. He became a naturalized citizen of the United States in 1948, since when he has been chairman of the Commission on Close Binary Systems of the International Astronomical Union and a member of the Commissions on Meteors and on Variable Stars, as well as of the sub-committee on the upper atmosphere of the National Advisory Committee on Aeronautics of the United States. Since 1950 he has been consulting editor of the *Journal of Mathematics and Physics*.

Imperial College of Tropical Agriculture: Mr. A. B. Killick, C.M.G.

Mr. A. B. Killick, at present director of agriculture in Uganda, has been appointed professor of agriculture and director of studies at the Imperial College of Tropical Agriculture, Trinidad, British West Indies, and is expected to take up his duties early in 1952. Mr. Killick graduated from Wye College (University of London) and is also a past student of the Imperial College of Tropical Agriculture. He spent the early part of his career in Uganda, where he served as an agricultural officer from 1924 until 1936. He was then appointed deputy director of agriculture in Trinidad, leaving there in 1939 to take up a similar appointment in Tanganyika; in 1947 he was appointed to his present post in Uganda.

Lorenz Oken (1779–1851)

Despite his remarkable learning, Lorenz Oken, who died a century ago, on August 11, 1851, is remembered chiefly as the exponent of doctrines long since abandoned. He was born at Bohlsbach in Swabia on August 1, 1779. When a medical student of two years standing, he published his "Grundriss der Naturphilosophie" (1802)—an attempt to construct a biology which reflected the action of the mind. Regarding man as the summit and crown of Nature, his exaltation of the male led him to declare that "Ideally every child should be a boy". Though he was groping toward something which he understood but imperfectly, he showed some conception of protoplasm and cells in his essay "Über das Universum" (1808), describing the first transition "from the Inorganic into the Organic" as "the transformation into a cell".

Oken advanced the science of embryology and founded the biological journal *Isis* (1816–48), an organ of wide scope responsible for an "encyclopædic diffusion of knowledge". By prompting the first German Congress of Naturalists and Physicians in 1822, he initiated the annual meetings of men of science which now have their counterparts all over the world. He originated the vertebral theory of the skull, later expounded by Goethe and finally exploded by Huxley in 1858. He never knew financial security, and his candour earned him political enemies who were responsible for his dismissal from Jena and Munich. Given a professorship in the newly founded University of Zurich in 1833, he produced his thirteen-volume "Allgemeine Naturgeschichte". Though frequently in the wrong, Oken was an original thinker and teacher who stimulated others to scientific endeavour. His real name was 'Ockenfuss'.

Science and Religion

THE controversy between truth as revealed by 'religious insight' and the scientific attitude is clearly brought out in two recent articles in *The Fortnightly* (No. 1,015; July 1951). In a review of Prof. Barbara Wootton's book, "The Testament of Social Science", J. B. Coates declares that knowledge of a scientific kind is on an inferior level of being to the existential world of the creative spirit, the world of value and of communion between persons, and should be recognized as being instrumental to it. Coates implies that the tendency to make science supreme over religion and philosophy is usually an evidence of spiritual debasement as it is frequently marked by intellectual arrogance. In her reply to Mr. Coates, Prof. Barbara Wootton argues much more tolerantly that Mr. Coates has attacked a windmill of his own making and that both unique personal experience and facts collected by scientific probing are essential if man's behaviour and values are to be understood. On a subject of such importance it is hoped that these articles will lead to comments by others.

East African Industrial Research Board

THE eighth annual report of the East African Industrial Research Board, covering the year ended December 31, 1950, indicates that no new major investigations have been initiated, the technical staff having been fully occupied on investigations already in hand. Much analytical work has also been undertaken and many mineral ores again assayed on behalf of the Geological Survey of Uganda. Kyanite is now being calcined locally to give the more valuable product, mullite, from which a substantial production of high-grade refractories is expected to develop. The production of fired clay building materials on a much larger scale in the Nairobi area is imminent. Further work has been done on the manufacture of Broseley tiles from Kiambu sub-soil and finely ground quarry debris, and a small pilot plant is producing decorated domestic pottery using brushwork on a raw glaze, although the only large pottery operating in Kenya has closed down its plant. Production of soda-phosphate fertilizer is now established commercially, but further work is being carried out to eliminate a tendency of the briquettes to collapse on warming when the reagents are fired in a brick kiln, with consequent difficulty in obtaining even firing conditions. Further research has been carried out on the so-called 'fermentation' of fresh pyrethrum flowers to ascertain whether a special treatment could be applied to the freshly picked flower heads which would substantially increase their pyrethrin content. It appears, however, that unless the action is closely controlled, no marked increase in pyrethrin content can be expected, and such control could not easily be applied on a large scale.

Commonwealth Index of Scientific Translations

FOLLOWING resolutions passed at the British Commonwealth Scientific Official Conference in 1946 and the Royal Society Scientific Information Conference in 1948, the British Commonwealth of Nations Scientific Liaison Offices in London have started a Commonwealth index of scientific translations. Each of the Commonwealth countries has or will have an agency which is to maintain a central index of translations into English of published scientific papers, reports and journal articles which have been made by various organizations within the Commonwealth. Each agency collects details of translations made by the organizations in its own country which are co-operating in the scheme; the information is then passed to British Commonwealth of Nations Scientific Liaison Offices, London, where index cards are prepared and sent out to the agencies within the Commonwealth. Persons wishing to know if a certain translation is available should apply to the agency in their own country. So far the following agencies have been established: *United Kingdom*, ASLIB, 4 Palace Gate, London, W.8; *Canada*, Information Division, National Research Council, Ottawa; *Australia*, Information Service, Commonwealth Scientific and Industrial Research Organization, 314 Albert Street, East Melbourne; *New Zealand*, Information Bureau, Department of Scientific and Industrial Research, Wellington; *India*, Deputy Secretary, Ministry of Natural Resources and Scientific Research, Secretariat, New Delhi.

Preservation of Glass from Corrosion

A SHORT note by Max Unwin on the preservation of glass from the effects of weathering is contained in the April issue of the *Museums Journal*. In many instances, iridescence in glass is caused by carbon dioxide in the air or soil forming carbonic acid. This combines with the alkaline constituents of glass and causes decomposition of the surface which may ultimately lead to complete disintegration. The iridescent appearance is the result of an optical effect, and the lamination of the decayed surface may be eliminated by impregnating the surface with a medium optically continuous with the glass itself. The resin now used for this purpose is a polyvinyl acetate dissolved in toluol, prepared by Messrs. Hopkin and Williams, Ltd. Impregnation is effected by dipping the object for a short time in the resin solution.

Oil and Colour Chemists' Association

THE membership of the Oil and Colour Chemists' Association has increased so rapidly, and its *Journal*, published monthly, has so increased in size, that it has become necessary to establish a permanent office. Mr. R. H. Hamblin has been appointed general secretary, both to look after the general affairs of the Association and to deal with the editorial side of the *Journal*. All business inquiries and communications should therefore be addressed to him at the Association's new offices, Memorial Hall, Farringdon Street, London, E.C.4. The 1951 Conference of the

Association was held at Scarborough during May 29–June 2, and the technical side took the form of a symposium on pigment/vehicle relationships. The following honorary officers were appointed for the current year: *President*, Mr. L. O. Kekwick; *Hon. Secretary*, Mr. R. S. Law; *Hon. Treasurer*, Mr. N. A. Bennett; *Hon. Editor of the Journal*, Dr. R. F. Bowles.

Summer School on the Technology of Synthetic Resin Adhesives

A SUMMER SCHOOL on the technology of synthetic resin adhesives, organized by Aero Research, Ltd., Duxford, Cambridge, will be held during September 23–29 at Cambridge. There will be a choice of two courses: synthetic resin adhesives for the wood-working industries; and synthetic resin adhesives for the engineering, electrical manufacturing and allied industries. Lectures will be given in the University Engineering Department Lecture Theatre in the mornings, and most afternoons will be devoted to practical work and demonstrations at the factory at Duxford. Accommodation has been arranged at St. Catharine's College, Cambridge, and the inclusive fee for the school is 10 guineas. Further details can be obtained from Aero Research, Ltd., Duxford, Cambridge.

Conference of the International Association of University Professors and Lecturers

THE sixth conference of university teachers, organized by the International Association of University Professors and Lecturers, will be held in Nice during September 20–24 and will be open to members of the Association and to all others interested. The conference will meet under the chairmanship of Prof. A. Portmann, of the University of Basle, and the vice-chairmanship of Prof. F. Vito, of the Catholic University of Milan. The general aim, as of all the activities of the Association, is to foster the development of an academic fraternity, across the boundary lines of faculties, among the university teachers of all countries. In particular, three topics will be considered at the conference: academic freedom; relation between research in industry and in the universities; and the status of the university teacher. The address of the conference will be Centre Universitaire Méditerranéen, 65 Promenade des Anglais, Nice. The registration fee is 10*s*. Further details can be obtained from Mrs. Cecil, Secretary, I.A.U.P.L., 13 Old Square, Lincoln's Inn, London, W.C.2.

University of London

THE title of professor in the University of London has been conferred on the following in respect of the posts held by them at the Royal Veterinary College, London: Prof. H. Burrow, professor of veterinary medicine; and Prof. N. J. Scorgie, professor of veterinary hygiene. The title of reader in inorganic chemistry in the University has been conferred on Dr. A. J. E. Welch, in respect of the post held by him at the Imperial College of Science and Technology, London.

Clayton Awards for 1951 of the Institution of Mechanical Engineers

UNDER the Clayton Bequest, the Institution of Mechanical Engineers has recently made the following awards for 1951, amounting in all to about £3,800, for postgraduate training or research in mechanical engineering: *Clayton Fellowships*: B. E. L. Deckker (Birmingham), F. Ellis (London), J. Halling (Mitcham, Surrey), J. Houghton (Coventry), D. Howe (Bletchley, Bucks), G. Moss (London), H. Naylor (Baildon, Yorks) and M. Ruddick (Grays, Essex). *Clayton Grants*: J. Huddart (London), D. R. S. Rabley (Plymouth) and N. D. Thomson (Sheffield).

Announcements

WE regret to announce the death of Prof. A. J. Allmand, F.R.S., lately professor of chemistry in King's College, University of London, which occurred on August 4, aged sixty-six.

PROF. C. A. COULSON, professor of theoretical physics in King's College, University of London, has been elected Rouse Ball professor of mathematics in the University of Oxford as from January 1, 1952. Prof. Coulson went to his present post in 1947 (see *Nature*, May 10, 1947, p. 632).

DR. ANDREW WILSON, reader in applied pharmacology in University College, London, has been appointed professor of pharmacology in the University of Liverpool.

A SUMMER SCHOOL on relaxation methods will be held in the Imperial College of Science and Technology, London, S.W.7, during September 3–21. The school will be on similar lines to that held last year and will cover the numerical solution of linear algebraic equations, framework problems, Laplace's and Poisson's equations, the biharmonic equation, eigenvalue problems, the heat-conduction equation, etc. The fee for the course will be £10. Further details can be obtained from D. N. de G. Allen, at the Imperial College.

A CONFERENCE organized by the Food, Agriculture and Fine Chemicals Groups of the Society of Chemical Industry on "Problems Arising from the Use of Chemicals in Food" will be held at the Wellcome Research Institution, 183–193 Euston Road, London, N.W.1, during September 27–28. Forms of registration for the conference can be obtained from the Assistant Secretary, Society of Chemical Industry, 56 Victoria Street, London, S.W.1; the registration fee is 10*s*. for members of the Society of Chemical Industry and £2 for non-members.

A COLLOQUIUM on recent advances in the study of cosmic radiation will be held in the School of Cosmic Physics, Dublin Institute for Advanced Studies, during September 25–27. Formal lectures will be given in the mornings by Dr. G. D. Rochester, Dr. C. Ó Ceallaigh and Dr. E. P. George. In the afternoons there will be specialized discussions to which contributions will be made by the visiting lecturers and members of the School. Further particulars can be obtained from the Registrar of the Institute.

IMPERIAL Smelting Corporation, Ltd., are now producing fluorine gas compressed into steel cylinders at 400 lb./sq. in. pressure at their Avonmouth works. Inquiries should be directed to the Company at 37 Dover Street, London, W.1.

IN connexion with the review of Oliver Heaviside's "Electromagnetic Theory" published in *Nature* of July 28, p. 136, Messrs. E. and F. N. Spon, Ltd., state that this publication is now issued only by them, and they have the complete copyright in it.

SCIENCE IN BERLIN

During the seven days beginning May 24, a scientific conference was held in Berlin and was attended by delegates from many parts of the world. It was held under the patronage of the Burgomaster of Berlin, Prof. Ernst Reuter; the Senate of the City of Berlin; and the Plenipotentiary of the German Federal Republic, Dr. Heinrich Vockel. The Conference was organized with the support of the Gesellschaft Deutscher Chemiker, and its president, Prof. K. Ziegler, paid tribute to Prof. J. D'Ans who, as president of the Berlin branch of the Gesellschaft, had been largely responsible for the idea of holding the Conference and for its organization. The bodies which acted as hosts were: the Freie Universität Berlin, the Technische Universität Berlin, the Deutsche Forschungshochschule Berlin-Dahlem, the Ortsverband der Gesellschaft Deutscher Chemiker and the Berliner Physikalische Gesellschaft.

The Conference demonstrated very clearly that Berlin again has an important part to play in academic and scientific affairs, and it provided a valuable occasion for Berlin scientific workers to meet their colleagues from other parts of Germany and to discuss their scientific problems. It was the first major scientific conference to have been held in Berlin after the War, since most of the recent conferences have been held in the Federal Republic of Western Germany. It was attended by students of the Berlin Universities, including the Humboldt University in the Eastern Sector. Nearly 2,500 tickets were sold to participants, about 800 of these to residents of the Eastern Zone of Germany or the Eastern Sector of Berlin.

The scientific papers were formally divided into two main groups: the first on chemical problems in living processes; the second on problems of atomic physics, molecular physics and cosmogony. The large number of papers contributed at the Conference (some sixty or so in number) covered a wide range of chemistry, physics and physical techniques; eight of the papers were from the Eastern Zone of Germany and four from the Eastern Sector of Berlin.

The visiting foreign men of science, many of whom read papers, were: Prof. H. J. Hildebrand, University of California; Dr. J. R. Johnson, Cornell University; Dr. Miller, Minnesota Mining and Metallurgical Corporation; Prof. P. Niggli, Technische Hochschule, Zurich; Prof. J. A. Hedvall, Göteborg; Prof. R. Domenjoz, Saarbrucken; H. Nitschmann, Bern; Prof. H. S. W. Massey, London; Dr. F. P. Bowden, Cambridge; Prof. Chrétien, Paris.

The Conference was held in the premises of the Technical University (Berlin-Charlottenburg), and at the ceremonial gathering the rector, Prof. W. Pflaum, laid stress on the important part that the fundamental and exact sciences play in technology. Dr. Vockel said that he envied the natural scientists their comparatively simple task of discovering the natural laws which govern the physical world. He appealed for their understanding of, and sympathy for, the politician who is attempting the difficult and urgent task of discovering the laws which govern the social order. Dr. Tiburtius, as Senator for Education in the City of Berlin, spoke of the attitude of the State towards science, which should not be to harness it for political ends, but to co-operate with scientific workers and to assist them in the free pursuit of their researches. The other speakers were Prof. M. von Laue, president of the Kaiser-Wilhelm-Institut, Berlin-Dahlem; Prof. Ziegler; Prof. Hans von Kress, rector of the Free University. Prof. C. Ramsauer, president of the Berlin Physical Society, gave an account of the part which Berlin scientific men have played, particularly in modern physics and chemistry. Measured by any yardstick this is impressive, and it was interesting to note that of the total of thirty-four Nobel Prizes which have been awarded to German physicists and chemists, eleven were gained by Berlin scientific workers. Prof. P. Niggli (Switzerland) spoke on behalf of the foreign men of science and paid tribute to Berlin's record in the natural sciences.

The first session began with a paper on photosynthesis by Prof. O. Warburg, and the physics session on radioactivity, which was under the chairmanship of Prof. J. D'Ans and Prof. M. von Laue, was opened with a paper from Prof. O. Hahn. This opening session was attended by Major-General G. K. Bourne, General Officer Commanding Berlin (British Sector), by Dr. Vockel, and by representatives of the British, American and French Scientific Research Divisions.

Those attending the Conference worked hard during the day, and in the evenings were entertained at various social functions, both official and private. These included a reception given by Dr. Vockel; an evening at the ballet "Abraxas", followed by a reception given by the Senator for Education, the Rector of the Technical University and the Rector of the Free University. At this reception a presentation was made to Herr Werner Egk, composer of the ballet. A reception was also given by the Mayor and Senate of Berlin. In addition to this, there were student gatherings and entertainments. Visits were paid to various research laboratories, many of which are admirably equipped and which are carrying out work of a high standard.

The Conference was held in an atmosphere of lively interest and enthusiasm, and it was impressive to see how science can transcend all political difficulties. The attendance was very large; in the physics session, for example, it was well over a thousand, a big proportion being students. The whole Conference was admirably organized, and it reflects great credit on Prof. D'Ans and the organizing committees. It is clear that science in Berlin is very much alive, and tribute must be paid to the devotion and courage of those who have built it up under such difficult conditions.

F. P. Bowden

A CENTURY OF DEVELOPMENTS IN ENGINEERING

A "Joint Engineering Conference, 1951", organized by the Institutions of Civil, Mechanical, and Electrical Engineers, was held in London during June 4–15. A large number of papers reviewing the development of different branches of engineering during the past hundred years were read.

One group of papers dealt with mechanical engineering developments in the mercantile marine, on the railways, in the gas industry, in electricity power stations, in road transport vehicles and in the iron and steel industry. Mr. R. A. Crowe outlined the development of ship propulsion from the day when the naval "Seamanship Manual" stated categorically that "there is no greater fallacy than to suppose that ships can be navigated on long voyages without masts and sails", to the most recent developments in the application of gas turbines to marine propulsion. He believes that for many years to come the steam turbine is likely to remain unchallenged for the propulsion of large passenger liners. Mr. R. A. Riddles reviewed progress in railway mechanical engineering from the early pioneering days of the Stockton and Darlington Railway, the first public railway to employ locomotive traction, to the many attempts to improve the thermal efficiency of steam traction which have been made during the first half of the present century. Mr. F. M. Birks dealt with technical advances in the gas industry. He explained the advances from manually charged retorts to the successfully developed Glover–West and Woodall–Duckham systems of continuous vertical retorts, which are now responsible for about one-half of the gas output of the industry. A ton of Durham coal now yields 74 therms of gas, 20 therms of tar and 165 therms of saleable coke, the total products for sale having 86 per cent of the thermal value of the coal. Mr. Birks thinks that, economically, the gas industry has a promising future, as it is able to convert thermal energy for cooking purposes at a capital cost considerably less than half that required by any other system of distributed energy. Mr. Bask, in discussing mechanical plant for electricity power stations, said that fifty-three new power stations have been designed in Great Britain to come into operation during the period 1946–56. Anxiety about the rate of extraction of coal, oil and natural gases is giving a special impetus to the use of water-power resources and the more efficient use of other sources of power. Economic studies appear to justify the use of heat from atomic piles for base-load stations, and it seems that atomic piles in association with steam plant may become practicable in the near future.

Another group of papers dealt with hydro-electric power schemes and power station design and construction, the generation, transmission and distribution of electricity, applications of electricity to sea transport, the development and use of gas-pressure cables for high-voltage systems in Great Britain, electric traction and signalling, telecommunications, air radio, electrical measuring instruments, the British television service, radio masts and towers and progress in electric lighting.

Sir John Hacking, in his paper on the generation, transmission and distribution of electricity, said he believes that during the next twenty years there will be more development in the use of water power than in the use of any other kind of energy for electrical generation. Tidal power schemes such as the Severn Barrage have been investigated, but they suffer from the disadvantage that it is not possible to obtain a reliable output during peak-load hours without some system of energy storage. On the other hand, the use of gas turbines would have the advantage that they can be started up rapidly for use during peak hours; they are not likely to become competitive in Great Britain until pulverized coal can be used as a fuel in the place of oil. Experiments are also being carried out at the present time to make use of wind power.

Mr. J. E. Goodall and Mr. D. B. Irving described the development of gas-pressure cables for high-voltage systems. The first experimental installation using high gas-pressure to suppress ionization, or the reaction involving re-combination of ions, passed its tests in November 1931, and the first commercial installation of this type of cable in the world was carried out in the following year in London. The main mechanical difficulties were encountered in sealing the ends; but these have now been largely overcome, and different manufacturers are standardizing the details of these cables.

Sir Stanley Angwin traced the development of telecommunications during the past hundred years, Air Commodore Cadell and Dr. O'Kane discussed the use of radio aids in flying, and Sir Archibald Gill described the ever-increasing use made of electrical devices on board ship. Sir Stanley Angwin pointed out that the electric telegraph handled 48,600 messages during the year 1851, whereas in 1948 that number had increased by more than a thousand times. The comparable figures for the telephone service show that the first exchange with eight subscribers was opened in 1879, the total number of subscribers increasing to 3,300,000 in 1939 and 5,200,000 at the present time. Dr. S. Whitehead reviewed the development of electrical measuring instruments. He pointed out that the early history of electrical measurements is virtually the history of physical science. Electrical measurements made many of the discoveries possible, which in turn led to better instruments. With the development of the electrical industry came a further great demand for reliable electrical measurements, until to-day there are very few measurements in which electricity does not or could not play a part. Sir Noel Ashbridge described the developments that led to the establishment of the British television service. He recalled that, in 1908, A. A. Campbell Swinton, in a letter in *Nature*, outlined a proposed method of television strikingly similar to that now in use. Sir Noel discussed the difficulties in the siting of television transmitters, and, turning to the future, thought that the reasons which militated against stereoscopic cinematography operate even more strongly against stereoscopic television. Colour transmission, on the other hand, presents an attractive field for development. It is now possible to transmit a satisfying picture of adequate detail in colour within the same spectrum space as a picture of apparently similar detail in monochrome.

Mr. R. D. Ackerley outlined the development of electric lighting from the discovery of the electric arc by Sir Humphry Davy to the construction of the largest light source in the world, a 4,000-amp. 600-kW. arc lamp for anti-aircraft use in the Second World War. The greatly improved efficiencies of modern lamps were mentioned, and Mr. Ackerley foresees developments in high-pressure mercury vapour lamps for better street lighting, and an increase in efficiency and a fall in the cost of fluorescent lamps. Mr. C. O. Boyse, in his paper on radio masts and towers, described the co-operation between the radio engineer and the structural engineer which is necessary in the design of these structures. He considers that the installation at Rugby, which was built in 1923 and consists of a dozen 820-ft. high masts, is still one of the outstanding achievements in this field.

Yet another group of papers dealt with permanent-way developments, underground-railway planning and railway bridges, ports, harbours and dry docks, road planning and safety, a number of public-health topics and the development and design of aircraft structures, and planning and construction of airfields. Mr. Everard, Mr. Anderson and Mr. Sutherland Campbell, the authors of the first of these papers, pointed out that underground railways provide a second plane of traffic with the highest known capacity for handling large crowds. They can handle more than 100,000 people per rush hour in two directions of traffic at an average speed of 20–25 m.p.h. The figures of journeys by public transport per year per head of population were given as: Paris 400, New York 462, London 500. No large-span railway bridge has been built in Great Britain since the Forth Bridge (1890). The greatest problem in connexion with railway bridges in Britain is their maintenance, the railway executive being responsible for a total of more than sixty-two thousand bridges. Mr. Leighton and Mr. Guthrie Brown discussed the port facilities of Britain and the great contribution engineers have also made to the handling of bulk cargoes like grain, seeds, coal and petroleum. There are now thirty-two major dry docks in the world, ten of which are within the British Commonwealth. Any forecast of future dry docks is linked with the average increase in the size of commercial vessels, particularly if the tendency of an increasing ratio of beam to length continues. Mr. G. T. Bennett, in his paper on road safety and planning, quoted an estimate that the total cost to Great Britain of road accidents was £100 millions in 1946, without accounting for losses due to delay on the roads. He pointed out that Great Britain depends for prosperity largely upon the exploitation of its geographical position, the short distances between ports and centres of industry favouring entrepot trade and exports. He advocated strongly the investment of capital in road improvement to cheapen production costs.

Mr. H. J. B. Manzoni, Mr. H. F. Cronin and Mr. D. M. Watson read three papers on the related topics of public-health engineering, water supplies and sewage disposal. Mr. Manzoni reviewed the insanitary state of most towns and cities in the early part of the last century and the great advances which have been made since then. He gave an indication of the magnitude of the problem of refuse disposal by quoting the figure of 14 million tons as the annual quantity of refuse collected by local authorities in England and Wales just before the Second World War. He also referred to the problem of district heating. This is the most economical method for a large estate of houses in which the whole of each house is heated; the cost is greater, however, than the cost of coal fires to heat only one, or at most two, of the rooms in each house.

Papers on engineering education and training which were read at the Conference have already been reviewed separately in *Nature* of July 7, p. 14.

E. K. Frankl

THE MUSEUMS ASSOCIATION

ANNUAL CONFERENCE

The fifty-seventh annual conference of the Museums Association was held in Belfast during June 18–22 under the presidency of Mr. S. D. Cleveland, deputy director, City Art Gallery, Manchester. The theme of the Conference in this Festival Year was "The Museum as Mirror of British Achievement in Art and Science". About three hundred delegates attended, including representatives of the French museum movement, and others from Unesco, and from Australia, Canada, Mauritius, Egypt and the United States.

The presidential address, on "Association Reflections", was a survey of the activities of the Association since 1939. Mr. Cleveland reviewed in some detail the work carried out by museums and art galleries during the difficult war years, and felt that, despite the handicaps, the period was a stimulating one in the museum movement. With regard to the future, Mr. Cleveland considered that, in adopting a constitution more in keeping with the present policy of the Association as primarily a professional organization, the present standards of curatorship necessary for a public service would be maintained and indeed improved.

Mr. J. A. S. Stendall, director of the Museum and Art Gallery, Belfast, after outlining the history of museums in Northern Ireland, described the modern display methods adopted at Belfast during the past few years. The material has been re-arranged so as to tell a story, colour effects have been used lavishly, and fluorescent lighting is combined with the earlier tungsten lamps. Reference was made to the projected museum of Ulster life and tradition which is to be established in the grounds of Belfast Castle.

Dr. D. Dilwyn John, director of the National Museum of Wales, recalling the theme of the Conference, reminded the audience that "a mirror reflects things outside itself and thus museums do mirror British achievements which are not in themselves museum achievements". As an example he took a specimen of *Glossopteris*, a fossil fern from the Antarctic, collected at the side of the Beardmore Glacier by Wilson when returning with Scott from the South Pole. Eventually the specimens were found and shown in the British Museum (Natural History). The fern proved the existence in former times of a great southern continent. But the fossil has another value, for it reflects and mirrors a great British achievement.

Dividing the work of museums into display, curatorial activity and study, Dr. John showed how present display methods consist of starting with the familiar and gradually passing step by step to the less well-known. The safety and preservation of rare specimens are among the most important of curatorial activities, while from the study of great natural history collections springs new knowledge and understanding. Dr. John stressed that a museum man, working in a natural history museum, may be led on from his fundamental work to considerations of the widest interest and to problems which are world wide.

Dr. F. Sherwood Taylor, director of the Science Museum, London, considered that local museums should show illustrations of the physical sciences even if only as temporary displays. He considered that experiments are preferable to static apparatus and stressed that museums should not attempt what has already been demonstrated in schools. He also felt it more desirable to illustrate local industries rather than the simple laws of physical sciences.

The Conference was of particular importance in that it not only reflected the continued progress of museums in their recovery from war damage and reorganization, but also demonstrated the new aims and ideas, techniques and activities which are now evident, and which have greatly stimulated popular interest in, and change of outlook towards, the function of public museums and art galleries.

INSTITUTE OF PHYSICS

ANNUAL GENERAL MEETING

AT the thirty-first annual general meeting of the Institute of Physics, held on May 16 at the Institute's House, 47 Belgrave Square, London, S.W.1, the following were elected to take office on October 1: *President*, Prof. W. E. Curtis; *Vice-President*, Dr. J. Topping; *Honorary Treasurer*, Mr. E. R. Davies; *Honorary Secretary*, Dr. B. P. Dudding; *New Ordinary Members of the Board*, Mr. O. W. Humphreys and Prof. S. H. Piper. Dr. A. B. Wood and Mr. C. G. Wynne join the Board as the new representatives of the Physical Society.

The thirty-first annual report of the Board, covering the work of the Institute during 1950, was adopted at the meeting. It records continued progress. The Board met six times and its various standing committees twenty-one times during the year. The total membership increased by 201 to 3,858, though there was a considerable—and from a financial point of view an undesirable—decrease in the number of subscribers. Slightly fewer applications for election or transfer to the various grades of membership of the Institute were received during 1950 than in the previous year. From the detailed analysis of membership given in the report, the effect of the changes made in the regulations in 1949 can clearly be seen. These changes allowed for the creation of the grade of graduate and the raising of the minimum ages of entry and the lengthening of the periods of experience required for grades of fellow and associate. It has recently been decided to establish a graduateship examination, and the regulations and syllabus, which have been drawn up by the Institute's Education Committee, will shortly be issued.

Details of the activities of the eight branches and the seven specialist subject groups of the Institute are listed in the report. The Australian Branch, which consists of five divisions, held thirty-three meetings for lectures and discussions, and, in addition, a four-day conference in Sydney during November on photometry and its applications. The Manchester and District Branch, in collaboration with the British Society of Rheology, held a summer conference on the physics of lubrication, and the Midland Branch held a two-day conference in Birmingham on vacuum physics at which several firms exhibited various types of vacuum equipment. Under the auspices of the Scottish Branch, well-attended courses of lectures on atomic and nuclear physics, and on industrial and medical applications of atomic physics, were given at the University of Glasgow and University College, Dundee, respectively.

Most of the groups, in addition to holding lecture meetings, organized or participated in conferences lasting over several days. The Education Group discussed physics in schools; the Electronics Group, gas discharge tubes; the Stress Analysis Group, electric strain-gauge techniques; and the X-Ray Analysis Group, both the production and application of high-intensity X-ray beams, and the development and application of Fourier methods in crystal structure analysis. The Industrial Radiology Group held a five-day summer meeting and exhibition in London in association with the Sixth International Congress of Radiology. This group has also been responsible for the production of memoranda on the training of industrial radiographers and on radiological units, in addition to the publication of a second edition of the "Handbook of Industrial Radiology".

At the suggestion of the British Iron and Steel Research Association, the Institute organized a conference on some aspects of fluid flow. This was held at the British Iron and Steel Federation's house, Ashorne Hill, near Leamington Spa, during October 25–28 and was attended by about a hundred and fifty, of whom one-third were members of the Institute. The papers presented and a summary of the proceedings are being published in book form by Messrs. Edward Arnold and Co.

The report mentions that thirty-three technical colleges have now received official recognition, after inspection by the Institute, as institutions suitable for the training of physicists. During 1950, for the first time candidates were presented for the Higher National Certificate in Applied Physics issued jointly by the Ministry of Education and the Institute, and four of the six candidates were successful. For the Ordinary National Certificate there were sixty-four candidates from England and Wales; thirty-eight were successful. Seven candidates entered for the first examination to be held in Scotland, and six were successful.

The Institute has continued to take an active part in the discussions by various bodies on the training of technicians and on higher technological education. The Board has decided to discontinue the Institute's Certificate in Laboratory Arts, and no further examinations will be held after December 1951. The proposals put forward by the City and Guilds of London Institute's Advisory Committee on the education and training of laboratory technicians for an appropriate examination under the auspices of that Institute are regarded by the Board as very satisfactory and suitable for replacing the Certificate examination.

The report states that the new monthly periodical, *British Journal of Applied Physics*, which began publication in January 1950, has been well received. Both in this journal and in the *Journal of Scientific Instruments*, a high standard has been maintained. Other publications during 1950 include a monthly *Bulletin* circulated to members; "Acceleration of Particles to High Energies", in the "Physics in Industry" series, containing the papers delivered at the symposium held in 1949 by the Electronics Group; and a revised and enlarged edition of "Notes on the Preparation of Contributions to the Institute's Journals and Other Publications".

The Institute has kept in close and constant touch with the American Institute of Physics, and is represented on many joint committees and bodies, including committees of the Royal Society and the British Standards Institution.

A growing number of inquiries from members and others about salaries, conditions of service, consulting fees, insurance and radiation hazards, and other professional matters were received and dealt with by the executive officers of the Institute. At the annual conference of the Branch and Group officers, the Board was requested to develop further the Institute's already extensive professional activities and to include a greater interest in the economic status of physicists, particularly those who are teachers in schools. A new survey, similar to that of 1948, of salaries and emoluments paid to Fellows and Associates is to be undertaken, and a new set of notes on terms of engagement suitable for physicists is being prepared. The appointments register has been discontinued, but notices of vacancies for physicists have been included in the monthly *Bulletin*, and from the steadily increasing demand from employers for such space it would appear that this new procedure is satisfactory.

FIRST NATIONAL POLISH SCIENCE CONGRESS

THE First National Polish Science Congress was held at Warsaw during June 29–July 2, in the magnificent hall of the reconstructed Polytechnic Institute. The Congress was called together to deal chiefly with the reorganization of science in Poland, and the discussions, therefore, concerned administrative problems rather than the details of scientific researches as such. Nevertheless, it was of great importance for Polish science, which lost some 40 per cent of its personnel, and suffered widespread destruction of buildings and equipment in the Second World War. Re-organization was required by the great expansion of facilities and numbers of newly trained scientific workers. It had come to be felt on all hands that a unified National Academy of Sciences was a necessity.

The principal formal business of the Congress consisted, therefore, in the incorporation of the former leading scientific organizations, such as the Cracow Academy of Sciences (Polskie Akademie Umietnosci) and the Scientific Society of Warsaw (Warszawska Towarzystwo Naukowe), both dating from the early years of the nineteenth century, into the new National Academy. The Cracow Academy had always been an honorific and essentially publishing body, while the Warsaw Society, though partly concerned with popularization of science (like the British Association), had come to possess a number of research institutes of its own. The new National Academy, modelled on those of the U.S.S.R., China and other countries, will now possess a network of research institutes, and the academicians will be mainly directors of institutes or departments of institutes.

Preparations for the Congress had involved more than a hundred conferences and meetings covering all branches of science and technology. At these meetings there had been discussion of the best arrangements for the organization of the new institutes. At the Congress itself it was emphasized, in the speech of the president (Dr. Jan Dembowski, zoologist), that during the period of re-organization there would be the minimum interruption of research projects currently under way. But besides these problems, the preliminary meetings had evidently also devoted much time to discussion of theoretical problems in the various sciences—a process no doubt stimulated by the desire of the younger generation of Polish men of science to incorporate the philosophy of dialectical materialism into the background of their thought. The interesting speeches of Dr. Dembowski and of Dr. K. Petruszewicz at the opening plenary sessions were made available to foreign representatives in languages of Western Europe, and it would seem very desirable that they should be published in some way in Great Britain.

Foreign countries were represented by small groups of up to about half a dozen members. The Soviet delegation, headed by Prof. Oparin, the biochemist, was naturally the largest; but there were also delegations from France, Germany, China, Hungary, Sweden, Rumania, etc. From the United Kingdom, Dr. J. Needham brought a message of greetings to the new National Academy from Prof. E. D. Adrian, president of the Royal Society. The foreign representatives were able to listen to the speeches in simultaneous translation, and had the opportunity of meeting a very large number of Polish scientific workers of all generations and all specialities. There can be no doubt that the Congress, and the Academy which it was called upon to found, represent an important step forward in the organization of science in Poland.

J. NEEDHAM

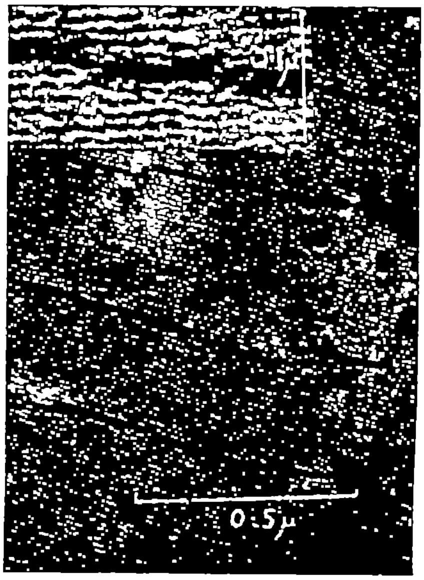
CRYSTAL STRUCTURE OF A LOW MOLECULAR WEIGHT PROTEIN

Electron Microscopy of β-Lactoglobulin Crystals

ELECTRON microscopy of protein crystals has in the past been concerned solely with proteins or nucleoproteins of high molecular weight[1-3]. In this investigation the electron microscope reveals structure in crystals of a protein of a much lower molecular weight, namely, β-lactoglobulin, molecular weight 36,000, which has already been examined by X-ray diffraction methods[4].

Preparations for the electron microscope were made according to the pseudo-replica technique of Wyckoff[5], the specimens being shadow-cast with palladium before stripping from the glass surface. The bulk of lactoglobulin was dissolved out in water before examination of the replica.

The accompanying micrograph is typical of the results. It shows the (100) face. The striations on the crystal face are parallel to the *b*-axis of the crystal. The periodicity is 105 ± 5 A. Molecular steps similar to those shown in earlier published pictures of *n*-hexatriacontane[5,6] occur on the crystal



face. From measurement of shadow-length these steps are found to 50 ± 10 A. in height. The micrograph therefore resolves structure in two crystallographic directions, namely, along *a* and along *c* on the crystal face. It is further evident from the micrograph that the molecules in the crystal are arranged in successive columns parallel to the *b*-axial direction, and this is confirmed by the fact that cross-shadowing does not improve resolution along *b*. It can be seen that the individual columns are in some instances incomplete; the inset enlargement gives two examples of this type of edge dislocation in the crystal lattice.

A direct comparison of the data from X-ray analysis and from electron microscope examination is now possible for the first time for this protein. Since the crystals of β-lactoglobulin were of necessity dried before examination, the results from them can be compared only with the X-ray diffraction results[7] from air-dried preparations. Such results are now given again in the following communication from Dr. D. P. Riley. The periodicity agrees well with previously recorded values for the *c*-axial length[7,8], as does the height of the molecular steps with the *a*-axial value. The concept of molecular packing in columns is supported by the (100) Patterson section given in the accompanying letter.

I wish to thank Prof. J. M. Robertson for his interest and encouragement in this work, the Rockefeller Foundation for an equipment grant to the Department, and Imperial Chemical Industries, Ltd., for a research fellowship. I am grateful to Mrs. D. Hodgkin for the specimen of β-lactoglobulin and for making available to me the X-ray data published in thesis form.

Structure of Dry β-Lactoglobulin Crystals

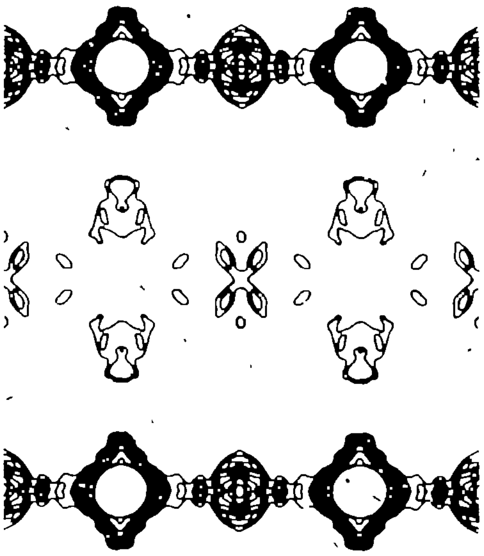
I AM encouraged by Dr. Dawson's most interesting communication to present some crystallographic results on β-lactoglobulin which have hitherto only been available in a thesis[1] or in articles[2] mainly of a review character. Attention will be confined to the dry orthorhombic crystals, often described as 'tabular'.

Although I have not examined the actual batch used by Dawson, the habit of his crystals is essentially the same as that of crystals which I have investigated from several other sources and may be written as: tabular $\{100\}$ elongated along $[010]$; strongly developed $\{100\}$ with subsidiary $\{001\}$ and indefinite $\{0kl\}$. The crystals show a pseudo-uniaxial interference figure and appear isotropic when viewed along *c* parallel to α.

The unit-cell dimensions of the air-dry crystals are $a = 60$ A., $b = 63$ A., $c = 110$ A. (N.B. The values given in an earlier note[7] are incorrect.) Values in good agreement with these have been reported since by other workers: Fankuchen[4], $a = 60$ A., $b = 62$ A., $c = 111$ A.; Senti and Warner[5], $a = 60{\cdot}7$ A., $b = 61{\cdot}0$ A., $c = 112{\cdot}4$ A. Perfect agreement would not be expected owing to the differences in residual water-content from crystal to crystal.

The relative intensities of 142 *hkl* reflexions have been estimated visually and used to calculate the principal Patterson projections and Patterson–Harker sections. That the structure of the air-dry crystals is not very disordered is demonstrated by the fact that X-ray reflexions occur out to a spacing limit of about 4·5 A. The space group is $P\,2_1\,2_1\,2_1$. The density of the air-dry crystals was measured as $1{\cdot}27 \pm 0{\cdot}01$, but the later figure of McMeekin and Warner[6], $1{\cdot}260 \pm 0{\cdot}003$, is more precise.

Dawson's unit-cell dimensions are $a = 50 \pm 10$ A., *b* undetermined, $c = 105 \pm 5$ A. It is to be expected that these values would be somewhat lower than those given by X-ray measurements on air-dry crystals, as the electron-microscope shadowing technique probably involves further drying in a vacuum chamber. The air-dry crystals still contain[6] 9·78 per cent of water by weight.



Patterson section at $x = 0$, $P\,(0, y, z)$, for air-dry lactoglobulin crystals. $b = 63$ A., horizontal; $c = 110$ A., vertical. Higher contours around origin not drawn

The agreement between the electron micrograph and X-ray diffraction evidence is not confined to this near coincidence of unit-cell dimensions. The accompanying figure reproduces the Patterson section at $x = 0$, $P\,(0, y, z)$, in which only the higher contours have been drawn, the lowest contour line shown having a value of 10 arbitrary units. For clarity, the very dense region around the origin has been omitted as the contours there rise to a value of 49. This map represents the summation of interatomic vectors lying in the (100) plane and is therefore directly comparable with the electron micrograph. Its main features are the pronounced band of vector density parallel to *b* at $z = 0$ and, conversely, the absence of any very high peaks in the middle of the pattern. This is exactly the Patterson vector-map corresponding to the arrangement of molecules shown in the micrograph, wherein the molecules lie in columns parallel to b, the columns being separated, centre-to-centre, by the whole c cell-dimension. The Patterson section, however, reflects further structure in the (100) layers which the electron micrograph is unable to resolve. There is, first, the fundamental b-lattice translation. Second, the relatively high peak at $y = \frac{1}{2}$, $z = 0$ shows that the molecules which constitute the columns parallel to b are probably placed with their centres $b/2 = 31 \cdot 5$ A. apart, that is, there is a pseudo-halving of this cell dimension. Third, the two distinctly resolved peaks on the $z = 0$ line, at 10 A. and at $b/2 - 10$ A., indicate the presence of marked intramolecular vectors parallel to b of length 10 A.

On the basis of eight molecules in the unit cell, the anhydrous molecular weight is 35,800, the errors arising particularly from imprecise knowledge of the water-content. Senti and Warner[5] arrive at the more accurate value of 35,400 from consideration of the wet crystals. The volume of the anhydrous molecule, subject to the same errors, is 44,400 A.^{3}, and it can be shown that 85 per cent of the available free volume in the air-dry crystal is occupied by water.

Reliable knowledge of the shape of the molecule with its actual linear dimensions is now clearly very near and should result from a re-examination of the X-ray data in conjunction with further electron micrographs.

SMITHSONIAN INSTITUTION

ANNUAL REPORT FOR 1949–50

THE report of the Secretary of the Smithsonian Institution for the year ended June 30, 1950*, points out that increasing pressures on all sides and definite trends in certain countries towards the regimentation of science enhance the importance of the freedom of inquiry which the Institution has always sought to further, and it records that government support of the ten branches of the Institution has not kept pace with modern exigencies, particularly in physical plant and facilities.

Reference is again made to congestion at the National Museum and at the Natural History and the Arts and Industries Building. The task of modernizing exhibits in the museums, which were visited by more than 2,600,000 persons during the year, is now proceeding as rapidly as funds become available for the purpose. The collections at the National Museum were increased by about 793,300 specimens during the year, while, in the field, investigations of the bird life of northern Colombia and of eastern Panama continued. Natural history collections were made on Prince Patrick Island in the Canadian Arctic archipelago, and other work has included a short field study of molluscs inhabiting the salt marshes on the eastern shore of Maryland, botanical field studies on Big Pine Key, Florida, extensive collections of lichens under the auspices of the Arctic Institute of North America, and a study of the origin and occurrence of rare sulphate minerals at the Geysers and Island Mountain, California; four field parties studied problems in invertebrate palæontology.

The Director of the Bureau of American Ethnology continued his studies of archæological collections made in Panama, and the survey work of the Bureau for the year has covered twenty-six reservoirs situated in eight States and five river basins. At the end of the year, excavations were completed or under way in thirteen reservoir areas in nine States, and, since the start of this River Basin Survey in July 1946, 120 reports have been issued, the investigations being conducted in co-operation with the National Park Service, the Bureau of Reclamation of the Department of the Interior, the Corps of Engineers and other non-government institutions. Archæological investigations conducted on Cornwallis Island in the Canadian Arctic have yielded a large collection of artefacts which have thrown considerable light on the prehistoric inhabitants of the region; further studies were made of the Iroquois, especially at the Tonawanda and Alleghany Seneca reservations in western New York, and Dr. J. P. Harrington continued his study of the grammar of the Abnaki language at Old Town, Maine. The Institute of Social Anthropology continued its anthropological teaching and research programmes in Brazil, Colombia, Mexico and Peru, and issued during the year Vol. 5 of the "Handbook of South American Indians".

The International Exchange Service handled 1,009,675 packages of government, literary and scientific publications, an increase of about twenty per cent, and the majority of the publications now being transmitted are current issues. Consignments are now made to all countries except Rumania and China, and ninety-nine sets of United States official publications are now sent abroad in exchange for similar publications of other countries, fifty-nine of these being full sets. A list of depositories of the sets is given in the report. The value of the National Zoological Park has been enhanced by addition of a number of animals never before exhibited there, and research has continued to be an important feature of its operations. At the Astrophysical Observatory the Division of Radiation and Organisms completed its reorganization and reconstruction of its laboratories; and the Division of Astrophysical Research, besides constructing three silver-disk pyrheliometers for institutions in New Zealand, Venezuela and Rumania, and two modified Angström pyrheliometers and a special water-vapour spectroscope for a meteorological institute in Belgium, has calculated that there has been an increase of 0·25 per cent in the radiation emitted by the sun in the two decades 1925–44 from solar-constant determinations at the Chilean station.

Twenty-one scientific workers visited Barro Colorado Island in the Canal Zone Biological Area during the year and worked at various research projects. The Smithsonian Library received 53,035 publications during the year and currently enters 16,961 periodicals, mostly in exchange for its own publications. With the Secretary's report is included the financial report of the executive committee of the Board of Regents.

* Report of the Secretary of the Smithsonian Institution and Financial Report of the Executive Committee of the Board of Regents for the Year ended June 30, 1950. (Publication 4020.) Pp. ix+161. (Washington, D.C.: Govt. Printing Office, 1950.) 50 cents.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Origin of the Word 'Protein'

In an address to the Swedish Royal Academy of Sciences on "The Place of Berzelius in the History of Chemistry" and in the Berzelius Memorial Lecture to the Royal Society, I claimed for Berzelius the authorship of the word 'protein'. This claim was based on the following passages in a letter to Mulder, the Dutch chemist, dated July 10, 1838:

"Or je présume que l'oxyde organique, qui est la base de la fibrine et de l'albumine (et auquel il faut donner un nom particulier p. ex. protéine) est composé d'un radical ternaire, combiné avec de l'oxygène dans quelqu'un de ses rapports simples que la nature inorganique nous présente."

And later in the same letter:

"Le nom protéine que je vous propose pour l'oxyde organique de la fibrine et de l'albumine, je voulais le dériver de πρωτειος parce qu'il paraît être la substance primitive ou principale de la nutrition animale que les plantes préparent pour les herbivores et que ceux-ci fournissent ensuite aux carnassiers."

Prof. A. C. Chibnall then pointed out to me that the credit for coining the word 'protein' was generally given to Mulder, and that the "Oxford English Dictionary" gives a reference to the first use of the word in his paper "Sur la composition des quelques substance animales" in the monthly issue of the *Bulletin des Sciences physiques et naturelles en Néerlande* dated July 30, 1838. The word 'protein' first occurs in print in this paper in the following sentence:

"La matière organique, étant un principe général de toutes les parties constituantes du corps animal, et se trouvant comme nous verrons tantôt, dans le règne végétal, pourrait se nommer Protéine de πρωτειος primarius."

The parallelism between these passages seemed to me too close to be an accidental coincidence; but a study of the Berzelius–Mulder correspondence edited by the late Dr. Söderbaum and published by the Swedish Royal Academy of Sciences brought to light no previous mention of the word 'protein' by either of them. Dr. Arne Holmberg, librarian of the Academy, then very kindly examined the post-marks on the Berzelius letter of July 10, 1838, which showed that it reached Greifswald on July 14, and although the post-mark at Rotterdam is illegible, the evidence of the transit time of another letter makes it probable that it reached Mulder by July 20. Mulder's paper opens with a generous acknowledgment of his debt to Berzelius, and there seems to me little doubt that he adopted Berzelius's suggestion without making any specific acknowledgment to him.

Prof. H. B. Vickery, in a paper on "The Origin of the Word Protein" in the *Yale Journal of Biology and Medicine* (22, No. 5; May 1950), examines the evidence in great detail and agrees with this view.

Thus, we owe to Berzelius in his later years not only the generalizations which he crystallized in the words 'isomerism', 'polymerism' and 'catalysis', but also the word 'protein' which he coined to express the fundamental significance of certain substances in nutrition, the sense in which we still use it to-day.

Observations of the Golgi Substance with the Electron Microscope

Observations by several investigators during the past few years lend support to the view that the Golgi substance is present in living cells in the form of droplets stainable supra-vitally with certain vital dyes[1-4]. The classical form of the Golgi substance has been considered to be a gross artefact induced by the development of myelin figures from droplets of phospholipid[3,4]. This view has been accepted by some[5-7] and questioned by others[8,9]. It was felt that observations with the electron microscope might aid in the elucidation of this complex problem. With this possibility in mind, liver and intestinal epithelium were fixed by perfusion in two different fixatives, one the Kolatchev–Nassonov modification of Champy's fluid[10] and the other a mixture of equal parts of 2 per cent osmic acid, 3 per cent potassium dichromate and 2 per cent lanthanum nitrate. The *p*H of the former fixative is 2·0 and that of the latter is 3·4. After fixation, slices of tissue were transferred to the same fixative for varying lengths of time. Both tissues were examined during the period of fixation with oil immersion at a thousand diameters by crushing the tissues under a coverslip in water or glycerine. Neither myelin figures nor the Golgi substance could be identified during the first twenty-four hours with the osmic acid, potassium dichromate, lanthanum nitrate mixture, nor during the first forty-eight hours fixation with modified Champy's fluid. Further treatment with 2 per cent osmic acid for three days at 37° C. resulted in the appearance of the Golgi substance with its typical form and distribution throughout both tissues after fixation in modified Champy's fluid but not after fixation in the osmic, dichromate, lanthanum mixture. Secondary treatment of the tissues preserved in the latter fixative with a mixture of equal parts of 3 per cent potassium dichromate and 1 per cent chromic acid followed by treatment with 2 per cent osmic acid for four days at 37° C. resulted in the development of faint positive images of the Golgi substance, whereas secondary treatment with modified Champy's fluid for twenty-four hours followed by treatment with 2 per cent osmic acid at 37° C. for four days resulted in the development of typical, well-blackened Golgi figures in both tissues.

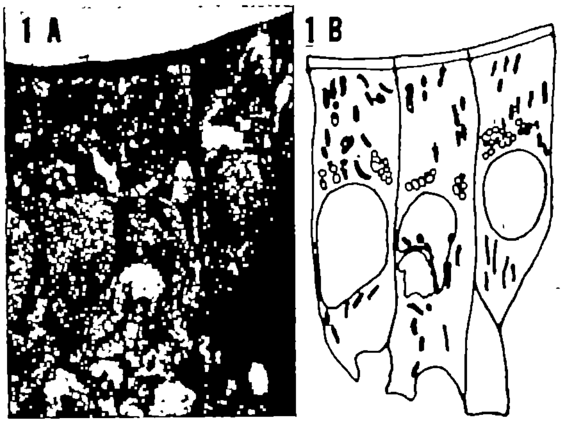

Fig. 1A. Electron micrograph of a principal cell of the duodenum fixed for twenty-four hours in modified Champy's fluid, showing empty vacuoles, arrow (osmiophobic component of the Golgi substance), in the Golgi zone (× 2,000 approx.). *B*. Tracing of the cell in Fig. 1A, to emphasize the vacuoles: mitochondria black

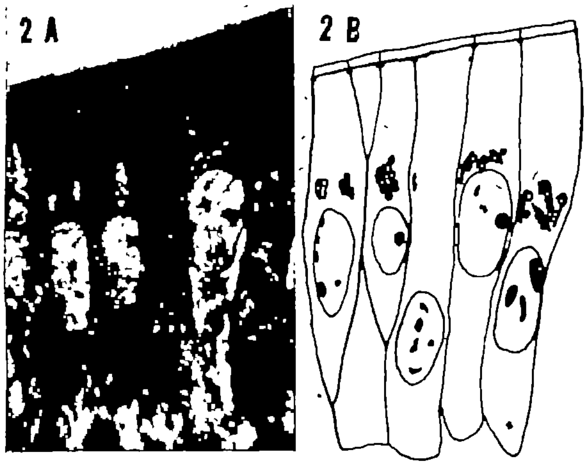

Fig. 2*A*. Electron micrograph of a principal cell of the duodenum fixed for twenty-four hours in modified Champy's fluid followed by treatment with 2 per cent osmic acid at 37° C. for three days, showing vacuoles comparable to those seen in Fig. 1 associated with osmiophilic material, arrow (osmiophilic component), in the surrounding cytoplasm (× 2,000 approx.). *B*. Tracing of the cell in Fig. 2*A* to emphasize the vacuoles and osmiophilic material

Examination of these tissues under the electron microscope disclosed the presence of negative images of the Golgi substance in principal cells of the intestine (Fig. 1) but not in hepatic cells after preliminary fixation in both fixatives. These negative images consisted of rows and groups of vacuoles, some showing slight darkening with osmic acid, others being completely empty. After treatment with osmic acid, positive images were found to consist of areas of blackened cytoplasm in juxtaposition to the vacuoles (Fig. 2). Few vacuoles were found in association with the Golgi substance in hepatic cells (Fig. 3).

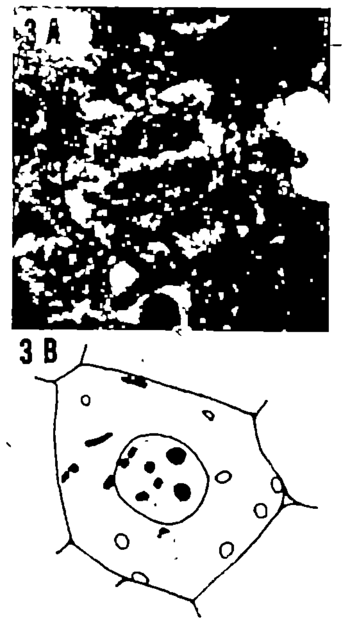

Fig. 3*A*. Electron micrograph of a hepatic cell fixed in modified Champy's fluid followed with treatment with 2 per cent osmic acid at 37° C. for three days, showing the osmiophilic component of the Golgi substance only, arrow (× 2,000 approx.). *B*. Tracing of the cell in Fig. 3*A* to emphasize the osmiophilic component of the Golgi substance. Osmiophilic spheroids (lipoid ?) in cytoplasm in outline form

Thus the Golgi substance is considered to consist of an osmiophilic and an osmiophobic component in principal cells of the intestine of the mouse, but frequently of an osmiophilic component only in hepatic cells. The osmiophilic component is believed to consist of a substance in the cytoplasm of the Golgi zone which reduces osmic acid only after treatment with a combination of strong oxidizing agents such as chromic acid, potassium dichromate and osmic acid. This characteristic distinguishes it from other substances in the cytoplasm which react directly and more readily with osmic acid.

These results suggest that the 'flexuose tubules' described by Gatenby in the hepatic cell of the rat[8] are not present in the hepatic cell of the mouse and that the osmiophilic component of the Golgi substance is not involved in myelin figure formation in the sense of Palade and Claude[3,4]. They also indicate that Baker's suggestion[5] of substituting the term 'lipochondria' for the term 'Golgi apparatus' because of the undesirability of continuing "to apply the name of the great Italian neurologist to an artefact" was possibly premature.

Superconductivity of Lead Isotopes

Before the discovery of the isotope effect in the superconductivity of mercury[1,2], it was generally assumed that the variation in the atomic weight (M) of a substance would not influence its transition temperature (T_c). This assumption was based on measurements by Onnes and Tuyn[3], and Justi[4], who had compared the transition temperatures of uranium lead and ordinary lead, and had found them to be identical. Observations of isotope shifts in the transition temperature of tin[5-7], and their agreement with the general theory of Fröhlich[8], make it probable that such an effect should also exist in lead. Assuming the validity of Frohlich's formula $T_c \propto 1/M^{1/2}$, the isotope shift in lead would be of the order of 0·025° K. This difference will have just escaped notice with the resolution used by Onnes and Tuyn, but could have been observed by Justi, who claimed an accuracy of temperature measurements to within several 1/1,000° K.

Measurements of the transition temperature have now been carried out on two lead samples with mean atomic weight of 206·15 and 207·72. The method[9] used was identical with that previously employed in this Laboratory, except that the gas thermometer readings were supplemented by a resistance thermometer. The disappearance of the electrical resistance of the two samples was found to be sharp to within 0·002° K., indicating good chemical purity of the metal. The transition temperature of lead-206·15 was found to be $0{\cdot}038_6 \pm 0{\cdot}002$° K.

higher than that of lead-207·72. No attempt has as yet been made to determine with great accuracy the absolute value of the transition points, which are slightly above 7·2° K. The resulting power of M(0·73 ± 0·05) thus appears to be somewhat higher in our experiments than that predicted by Fröhlich (0·5).

Lead-207·72 (extracted from Ceylon thorite)[10] was kindly lent to us by Prof. F. Soddy, and spectrographically analysed by Mr. G. H. Palmer, of the Atomic Energy Research Establishment, Harwell.

We are grateful to Mr. C. H. Collie for lending us the uranium lead sample (lead-206·15) which was obtained from the Eldorado Mining Company of Canada. I wish to thank Dr. K. Mendelssohn for his interest and advice, and my husband, J. L. Olsen, for his help with the experiments.

The Clock Paradox in Relativity Theory

THE clock paradox discussed by Prof. McCrea in his letter in *Nature* of April 28 is, as he says, no paradox at all. It exists only for observers who have been asleep during the changes of direction of motion of the clocks.

A stumbling-block to handling the problem by using the Lorentz transformations is that these apply only to uniform motion, not to a clock reversing its direction of travel. This difficulty may be avoided if we make use of auxiliary moving clocks, to which the epochs of the original clocks are communicated as they pass each other.

Consider two identical railway trains in uniform motion at different rates; call them *A* and *B*. Observers on these trains make indistinguishable observations of uniform separation or approach. For convenience, locate our co-ordinate system on *A*, that is, consider it stationary. At some point in the progress of *B* let another identical (auxiliary) train *C* pass it going in the opposite direction at such a rate that it ultimately passes *A*. Let the epoch on the clock on *B* be flashed to a clock on *C* as they pass. Then as *C* passes *A* (*B* meanwhile passing off into space), a comparison of the epochs of the clocks on *A* and *C* shows the clock on *C*—since *B* and *C* have both been in motion with respect to *A*—to be behind the clock on *A*. The observer on *A* sees a clock pass him in one direction, and if he has not seen the transfer operation, sees the clock returning, having lost time in the process.

For an observer on *B* the similar experience is presented, when at some point *A* is passed by a train *D* travelling at such a speed that it ultimately overtakes *B*. It reaches *B* by *travelling at a higher velocity* than *B*; the epoch of its clock, originally flashed from *A*, is retarded over *B* because of this higher velocity in travelling over the same distance.

The argument is as follows: Designate by *L* the distance between *A* and *B* when *D* catches up with *B*. The time is then L/v, where v is the velocity of *B*. Because of the slowing down of *B*'s clock, this time will be read:

$$t'_B = \frac{L}{v}\sqrt{1-\frac{v^2}{C^2}} \cong \frac{L}{v} - \frac{1}{2}\frac{Lv}{C^2}.$$

Now *D* traverses the distance *L* in time L/V, where V is *D*'s velocity. This will be read by *D*'s clock as:

$$t'_D = \frac{L}{V}\sqrt{1-\frac{V^2}{C^2}} \cong \frac{L}{V} - \frac{1}{2}\frac{LV}{C^2}.$$

D, however, received its epoch from *A* when *B* had already travelled some distance l, that is at the time l/v, so that the time read on *D* will be:

$$T'_D = t'_D + \frac{l}{v}.$$

Now $\frac{L-l}{v} = \frac{L}{V}$, or $\frac{l}{v} = \frac{L}{v} - \frac{L}{V}$;

so that we have:

$$T'_D = t'_D + \frac{l}{v} = \frac{L}{V} - \frac{1}{2}\frac{LV}{C^2} + \left(\frac{L}{v} - \frac{L}{V}\right)$$
$$= \frac{L}{v} - \frac{1}{2}\frac{LV}{C^2};$$

which is to be compared with t'_B above. Since V is greater than v, the time by *D*'s clock is less than the time by *B*'s clock.

Thus, *B* also observes a clock moving away from him, and later (not having observed the process of transferring epoch from *A* to *D*) sees 'the clock' returning, having lost time. Both observers conclude that it is the other's clock that has slowed down.

If in the first case an observer on *B* is (in a state of unconsciousness) trans-shipped from *B* to *C* at the same time that the interchange of clock readings is made, when he awakes he observes *A* approaching him. When he passes *A* he finds *his* clock is behind *A*'s clock, contrary to his expectation that since *A* has receded and approached it will be *A*'s clock that has lost. He thus discovers that he has been 'Shanghaied' while unconscious. The observer on *A*, as described above, similarly unconscious while the *B*—*C* transfer occurs, agrees with the *B*—*C* observer, when they meet, that the latter's clock has lost time—there is no clock paradox. The observer on *A* is also reassured, if he has followed this argument, that he has stayed on the same train during his nap.

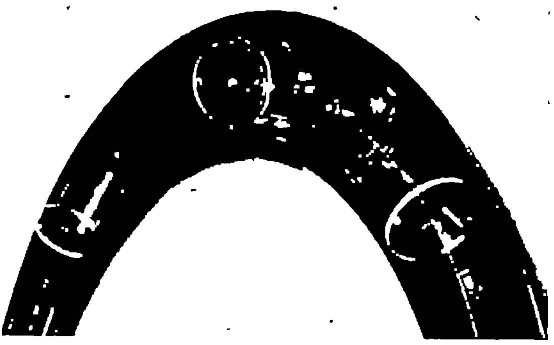
A Toroidal Geiger Counter

A TOROIDAL Geiger counter has been constructed in an attempt to produce a γ-ray sensitivity detector with a response independent of the position of the γ-ray source over a small region of space. The counter was made from two U-shaped half-sections (radius ¼ in.), one of which is shown in the photograph, pressed from 24 S.W.G. oxygen-free copper. The counter was designed in the first instance for experiments in which it was necessary to pass the counter freely over the human head, and for this reason a toroid of mean diameter 12 in. was made. The centre wire, of 0·008-in. diameter tungsten, was supported by eight equi-spaced 'Perspex' disks with central holes through which the wire was a push-fit. These insulators were keyed to one half-section of the counter by phosphor-bronze spigots which projected $\frac{1}{8}$ in. into the edges of the disks. The connexion to the centre wire was taken out through a metal-to-glass seal of commercial pattern, and the two halves of the counter were soldered together using solder-paste and 60/40 soft solder. No difficulty was found in making a vacuum-tight joint without excessive penetration of flux into the tube. A connexion to the vacuum system was made via a lead alloy stem, and the tubes were pumped and filled with a mixture of 10 per cent ethyl alcohol and 90 per cent argon to a pressure of 10 cm. mercury in the usual manner.



Half-section of a toroidal counter showing the lead-out insulator and the 'Perspex' disks supporting the centre wire

A typical counter has an operating threshold of 1,100 volts and a plateau of about 200 volts with a maximum slope of 0·06 per cent volt^{-1}. Unshielded, the background is about 1,000 counts min.$^{-1}$, which appears rather high considering the effective length of the counter; it may be that discharge effects over the 'Perspex' insulators contribute to the background count. In the plane of the counter, the counting-rate due to a small 1-μgm. γ-ray source of radium at the centre of the toroid is 2,500 min.$^{-1}$, which does not change more than ± 10 per cent from the mean for movements within a concentric circle of radius 8 cm. Outside this region the counting-rate increases, especially rapidly as the source approaches the counter wall. With a point source on the central axis at right-angles to the plane of the ring, the counting-rate does not change more than 5 per cent over distances of ± 5 cm. from the plane of the ring.

One interesting property of this counter is its response to γ-rays from the same amounts of radioactive salt dissolved in different quantities of solvents. For example, with 25 μc. quantities of radioiodine in volumes of water of 50–1,000 c.c. filling spherical flasks placed concentric with the counter, the counting-rate was the same (∼ 10,000 counts min.$^{-1}$) within 2 per cent in all cases. This result may be fortuitous, arising from the particular size of the counter which has been made; but it does suggest a simple apparatus for assessing the excretion of radioiodine in thyroid function analyses without making volumetric measurements.

Further details of the counter will be published later. At present, to find under what conditions a uniform sensitivity over a greater volume of space can be obtained, experiments are proceeding with two similar toroidal counters arranged in a system analogous to a Helmholtz coil.

Dielectric Behaviour of Human Blood at Microwave Frequencies

In the course of studies of microwave absorption in human tissues, measurements have been made of the dielectric constant, $\epsilon'-j\epsilon''$, of whole human blood at a number of frequencies in the range $1·78 \times 10^{8}$ c./s. to $2·36 \times 10^{10}$ c./s., employing co-axial-line and wave-guide methods described elsewhere[1,2]. The specimens used had red cell concentrations within the limits $4·9 \pm 0·1 \times 10^{6}$ cells per mm.[3] and were heparinized to prevent coagulation.

Dispersion was found to occur and the experimental results to agree, within experimental error (± 2 per cent in ϵ' and ± 5 per cent in ϵ''), with values calculated from the Debye equations with a single relaxation time, τ, if dielectric loss due to an ionic conductivity, σ_i, was allowed for. The values of ϵ^* (the value from which ϵ' falls in the dispersion region), ϵ_∞ (the value ϵ' asymptotically approaches at high frequencies), τ and σ_i which have been derived from the analysis of the results at three temperatures are shown in the accompanying table, together with corresponding values of ϵ^* and σ_i for blood plasma.

The dispersion observed can be attributed entirely to dipolar orientation of part of the water present in blood. The dispersion effects of inhomogeneity, investigated previously by others (see, for example, Danzer[3] and Schwan[4]), appear to be absent at microwave frequencies. The relaxation times shown in the table are approximately 8 per cent higher than the values for pure water at the same temperatures. Recent work[1] indicates that this increase is probably related to hydrogen-bond formation between water molecules and active groups of other molecules.

Temp. (° C.)	Whole blood				Blood plasma	
	ϵ^*	ϵ_∞	τ	σ_i ohm^{-1} cm.$^{-1}$	ϵ^* (calc.)	σ_i ohm^{-1} cm.$^{-1}$ (exp.)
15	62·0	4·5	$1·19 \times 10^{-11}$ sec.	0·010	78·3	0·0108
25	58·0	4·6	0·90 ,, ,,	0·012	74·3	0·0128
35	56·0	4·5	0·70 ,, ,,	0·014	70·6	0·0155

Further analysis of ϵ^* and σ_i for whole blood and plasma has been carried out by application of theories for inhomogeneous dielectrics. Those of Maxwell[5], Wiener[6] and Fricke[7] all lead to the relation

$$\frac{k - k_1}{k + xk_1} = \rho\,\frac{k_2 - k_1}{k_2 + xk_1},$$

when k, k_1 and k_2 are the dielectric constants or specific conductivities of the suspension, the suspending and the suspended media respectively, ρ is the volume concentration of the suspended medium and x is a numerical factor depending on the shape of the suspended particles and on the ratio k_2/k_1. Fricke[8] has shown the theory to hold in the cases of the low-frequency conductivity of blood and of cream up to a concentration of 62 per cent of cream in skimmed milk. It will be assumed that the theory also holds in the present case and that the effect of cell-membrane impedance is negligible at microwave frequencies.

Using the values of ϵ^* and the corresponding dielectric constants of blood plasma given in the table, and assuming the effect of cells other than erythrocytes is negligible, the above relation gives the dielectric constant of the contents of the red cell as 43·9, 40·1 and 39·8 at 15°, 25° and 35° C. respectively. Further, assuming the relation also applies to the cell contents and that a hæmoglobin molecule with its hydration sheath is an oblate spheroid of axial ratio 2, further use of the above equation gives the volume and hydration of the cell hæmoglobin. The mean value for hydration found from the results at the three temperatures is $0 \cdot 23 \pm 0 \cdot 16$ gm. water per gm. hæmoglobin. This is in fair agreement with the estimate derived by Haggis *et al.*[9] from microwave measurements on hæmoglobin solutions.

It is of interest to note that if the hydration is calculated by use of a simple volume proportion relation[10,11] for the dielectric constant of the cell contents, the estimate obtained is twice the figure quoted above.

In the case of ionic conductivity, application of the above law for inhomogeneous media using the conductivities given in the table shows that the ionic conductivity of the intracellular fluid is 83 per cent of that of the plasma. This is in good agreement with published data[12] for the ion balance of normal human erythrocytes and plasma, from which a ratio of 0·79 is obtained.

Full details of this work, and of corresponding microwave studies on human tissues, will be published elsewhere.

Relation between Polyploidy and the Amounts of Deoxynucleic Acid per Nucleus in the Liver and Kidney of Adult Rats

The nuclei of the livers of rats vary greatly in size, and it was found[1,2] that the nuclear volumes formed a geometric series of type 1, 2, 4. Beams and King[3] showed that the doubling of the nuclear volumes was due to polyploidy, so that within the cells of the liver there were nuclei which contained the diploid, tetraploid or octoploid number of chromosomes. In the liver of the adult rat, 70–80 per cent of the nuclei were tetraploid, and almost all the nuclei in the remaining 20–30 per cent were diploid with only a few per cent octoploid[1,2]. Mirsky and Ris[4] demonstrated that in tissues the deoxynucleic acid was situated in the chromosomes, and it was suggested that the amount of deoxynucleic acid per nucleus was related to the chromosome number. Therefore, a large proportion of the nuclei in the liver of the adult rat should contain twice the amount of deoxynucleic acid found in the diploid nucleus. No direct evidence has been obtained for the rat; but Swift[5] has shown in the adult mouse, by using the absorption of Feulgen-stained nuclei in histological sections as a measure of the amount of deoxynucleic acid per nucleus, that most of the nuclei in the liver contained twice the common amount of deoxynucleic acid which had been found in the small liver nuclei and in the nuclei of other tissues, including the kidney.

From the analyses of suspensions of nuclei it is only possible to obtain a mean value for the amount of deoxynucleic acid per nucleus. However, for the mammalian tissues so far investigated, it has been found that the mean amount of deoxynucleic acid per nucleus is always about 6×10^{-6} μgm.[6-8]. This value is presumably equal to the amount of deoxynucleic acid in the diploid nucleus. If the amount of deoxynucleic acid per nucleus is associated with the chromosome number, it should follow by simple proportion that, in the liver containing 70–80 per cent tetraploid nuclei, the mean amount of deoxynucleic acid per nucleus should lie between 10 and 11×10^{-6} μgm. deoxynucleic acid per nucleus (assuming that the percentage of octoploid nuclei is negligible). Values of this order were obtained by Dounce, Tishoff, Barnett and Freer[9] for rats of the Wistar strain. Further, it has recently been found that the mean amounts of deoxynucleic acid per nucleus in the livers of three male and three female black-and-white hooded rats, of mean weight 270 gm. and 205 gm., were 9·6 and $10 \cdot 2 \times 10^{-6}$ μgm. respectively. It is proposed to report these findings in more detail elsewhere.

In order to determine whether a relationship does exist between the amount of deoxynucleic acid and the number of chromosomes in the nucleus, it was decided to estimate in the same animals the mean amounts of deoxynucleic acid per nucleus in the kidney as well as in the liver, since the former tissue contains only nuclei with the diploid number of chromosomes. The livers and kidneys were removed from seven adult female black-and-white hooded rats of the Lister strain and of mean weight 200 gm. The samples of liver and of kidney cortex were each separately pooled for analysis. The nuclear suspensions were prepared by the method of Dounce[10] in an aqueous citric acid medium at pH 4. The deoxynucleic acid was estimated as deoxynucleic acid phosphorus after removing the acid-soluble, phospholipid and ribonucleic acid fractions[11]. The nuclei in the suspension were counted in a hæmacytometer, and from these results the mean amount of deoxynucleic acid per nucleus was deduced.

In the liver the mean amount of deoxynucleic acid was $10 \cdot 1 \times 10^{-6}$ μgm. per nucleus, whereas the mean amount in the kidney was $5 \cdot 7 \times 10^{-6}$ μgm. deoxynucleic acid per nucleus. The value for the kidney is in close agreement with that reported for the diploid nuclei. From these values for the liver and the kidney it may be calculated, assuming as before that the percentage of octoploid nuclei is negligible, that about 76 per cent of the nuclei contained the tetraploid number of chromosomes. This result agrees very closely with that observed histologically by Sulkin[1] and McKellar[2].

From the results it may be concluded that the high values which have been obtained for the mean amount of deoxynucleic acid per nucleus in the liver of the rat have been due to the presence of nuclei containing the tetraploid and octoploid number of chromosomes. The striking agreement between the values for the degree of polyploidy obtained by histological measurements and by calculation from chemical analyses suggests that a doubling in the number of chromosomes is accompanied by a doubling in the amount of deoxynucleic acid per nucleus. Therefore, it would appear that for the rat there is a direct relationship between the amount of deoxynucleic acid per nucleus and the number of chromosomes. The significance of these findings in the calculation of the mass of the liver cell will be discussed in a later paper.

Coenzyme of Kidney Phosphatase

IT has been deduced from dialysis at different *p*H that kidney phosphatase can be separated according to the scheme:

holophosphatase ⇌ coophosphatase + apophosphatase[1].

By mixing the dialysis liquid with the solution of inactivated phosphatase and adding magnesium, reactivations up to 100 per cent can be reached: by adding to the apoenzyme boiling solutions of the enzyme, in which the coenzyme remains unaltered, partial reactivations can also be obtained. Albers thinks that the coenzyme cannot be magnesium, but a labile organic substance which has not been identified.

These results have been ascribed alternatively to the presence of small amounts of zinc or cobalt ions, which are able to form a dissociable complex[2]. On the same lines, kidney phosphatase has been considered as an enzyme with dissociable metal (magnesium and also zinc) which may not contain a dissociable coenzyme; so the enzymatic activity would be connected with co-ordination in a metal complex of various fragments of the apoenzyme[3].

It has also been suggested that the dialysable prosthetic group could be a combination of a metal and a substance containing amino-acids; this has been inferred from experiments of reactivation of phosphatase with amino-acids in the presence of metallic ions[4]. But the active entity of boiled solutions cannot be replaced by amino-acids, according to another series of experiments[5].

Following our research on organic models of phosphatase[6] and in order to get a better knowledge of the composition of the enzyme, we have carried out experiments on the dialysis of kidney phosphatase. This was obtained by the Albers method, and we have verified previous results on inactivation, going further in the study of the dialysed liquid.

The liquid of acid dialysis, on evaporation *in vacuo*, gives a residue having 5·2 per cent nitrogen. The spectral analysis of the ash gives magnesium, zinc, nickel, calcium, iron, sodium and potassium—the same metals present in the phosphatase before dialysis[7], but which are not contained in the apoenzyme.

The same residue, treated with alcohol, deposits the mineral part—an insoluble white solid containing the metals referred to before, except magnesium. It also contains phosphorus (24·1 per cent of phosphate) corresponding to a formula PO_4HM^{II} with an average atomic weight of 30 for M^{II}.

From the filtrated solution a very hygroscopic organic residue (N = 10·7–11 per cent) containing magnesium can be crystallized (see accompanying illustration); it melts at 110–120° (with softening), is precipitated by ammonium molybdate and gives yellow needles, m.p. 180° (decomp.), with picric acid.

By treatment with hot, concentrated hydrochloric acid, another portion containing PO_4^{---} is separated, a pentose is identified and another nitrogen compound (N = 23·5 per cent), which is not precipitated with ammonium molybdate and picric acid, is isolated. The spectrum of this substance is now under study.

The results so far obtained suggest that kidney coophosphatase is a metallic derivative of a diphosphonucleoside, probably derived from adenosine, as can be deduced from analytical data and spectral analysis.

Adrenotropic Hormone (ACTH), Aminopterin and Eosinophil Count

Recent experiments indicate that a relationship might exist between aminopterin and adrenal cortex function. Dougherty and Dougherty[1] report that, following adrenalectomy, mice do not show the lymphopenia and acute atrophy of lymphatic tissue which are observed following a lethal dose of aminopterin. Higgins[2], using aminopterin and aminoteropterin, showed that adrenalectomy minimized considerably the changes induced by such drugs within the spleen, the thymus gland, the peripheral blood and bone marrow of rats. They assumed that some effects of aminopterin can be due to a stimulation of the adrenal cortex. On the other hand, Hanlon[3] of the Mayo Clinic has observed that aminopterin in human subjects gives a rather marked decrease in the output of corticosteroids and, in no case, an increase.

In our experiments we first attempted to see whether administration of adrenotropic hormone (ACTH) (kindly supplied by Irby Bunding, of the Biochemical Department, Armour and Company, Chicago, Illinois) would influence the survival time of mice injected with 50 mgm. per kgm. of aminopterin (kindly supplied by Dr. J. M. Ruegsegger, of the Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York).

Twelve albino mice (mean weight 20 gm.) were divided into two groups. Each mouse of the first group was injected with 1 mgm. of aminopterin intraperitoneally and these were used as controls. The mice of the second group received 1 mgm. of aminopterin intraperitoneally and 2 mgm. of ACTH intramuscularly, divided in two doses. The ACTH was then given to them in the same dosage every day until death occurred. All the animals of both groups died within the fourth day after the injection of aminopterin. No appreciable difference was detected in the time of survival between the animals not treated with ACTH and those which received 2 mgm. of ACTH daily. In other words, in our experiments a stimulation of the adrenal cortex by ACTH does not affect the toxicity of aminopterin, although an absence of its function has been stated to minimize the effects of the aminopterin and teropterin.

Another point we tried to establish was whether aminopterin could interfere with the response of the adrenal cortex to ACTH. The response of the adrenal cortex to the stimulation by the adrenocorticotropic hormone was tested by means of an eosinophil count. The eosinophils were stained by Pilot's method[4].

Experiments were performed on eight guinea pigs (mean weight 500 gm.). On each of the animals an eosinophil count was done. The following values were obtained: 116, 84, 90, 45, 160, 35, 214, 180. Then 1 mgm. of ACTH was given to each animal, and after four hours another eosinophil count gave the following results: 45, 50, 35, 10, 40, 0, 60, 70. In other words, all the animals showed a drop of eosinophils which was about one-half or more of the initial count.

Then each guinea pig received one mgm. of aminopterin intraperitoneally every day for five days. On the fifth day another eosinophil count was made on them and the following values were obtained: 45, 32, 64, 0, 700, 40, 0, 400, 27. (The two guinea pigs which showed an increased eosinophil count were found at necroscopy to be pregnant at a very early stage.) Then 1 mgm. of ACTH was given to each animal, and after four hours a new eosinophil count was made. The results were respectively: 10, 0, 3, 0, 120, 0, 0, 85, 0. In other words, the animals treated with aminopterin showed a normal response (so far as it can be determined through the eosinophil count method) of the adrenal cortex to ACTH. Since the decrease of eosinophils following ACTH in animals treated with aminopterin has been more marked than in the control animals, it might be assumed that the response to ACTH is increased in animals treated previously with aminopterin. This would concur with the findings of adrenal cortex hypertrophy in animals treated with aminopterin. On the other hand, it is difficult for us to explain the observation by Hanlon[3] of a decreased output of corticosteroids in patients treated with aminopterin, unless it might be caused by the difference in the dose of aminopterin.

I am grateful to Mr. Maurice Szafarowicz for technical assistance.

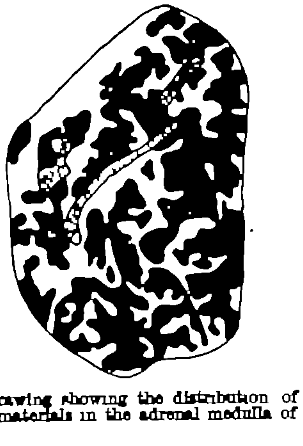
Histochemical Evidence of the Presence of Acid-Phosphatase-Positive and -Negative Cell Islets in the Adrenal Medulla of the Rat

Recent investigations have demonstrated the presence of *nor*adrenaline as well as adrenaline in the adrenal medulla of some mammals. In this communication, histochemical observations are reported indicating the presence of two different kinds of cell islets in the adrenal medulla of the rat.

The material consisted of about fifty adrenals of healthy rats. For the demonstration of acid phosphatase an improved technique[1] modified from Gomori's[2] procedure was used. This technique always gave reproducible results free of the capricious variations frequently characterizing the original method.

The greater part of the adrenal medulla contained large amounts of histochemically demonstrable acid phosphatase, already evident after immersion for 10 min. in the substrate solution. Another part, on the contrary, was still pale in sections treated for two hours in the substrate. The accompanying



Camera lucida drawing showing the distribution of acid-phosphatase-positive materials in the adrenal medulla of a male rat camera lucida drawing shows the distribution of phosphatase-positive and -negative substances, the former shown as black. In preparations stained by the ordinary histological methods, these tissues did not differ from each other and both of them were composed of typical chromaffin medullary cells.

The influence on the adrenal medulla of procedures stimulating medullary secretion was examined; for example, adrenals of rats killed during prolonged severe insulin shock were compared with those of normal controls. No certain qualitative differences could be seen. Therefore, areas of phosphatase-positive and -negative tissues were measured planimetrically in sections cut serially. These quantitative studies revealed a statistically significant increase in the volume of the phosphatase-negative tissues of the animals treated with insulin. The volumes of the phosphatase-positive tissues were approximately equal in both groups.

The presence of two kinds of medullary tissues can also be demonstrated with other histochemical techniques[3]. The phosphatase-negative islets are selectively darkened by a short immersion in ammoniacal silver nitrate and they fluoresce brilliantly in ultra-violet light. The significance of the two types of islets is not clear; but both of them have hitherto been seen only in species the adrenals of which contain both *nor*adrenaline and adrenaline.

Further work is in progress.

Methylation of a Phenolic Hydroxyl Group in the Human Body

In the course of clinical trials of the antithyroxine compound, *n*-butyl 3 : 5-diiodo-4-hydroxybenzoate[1], on patients with thyrotoxicosis, the nature of the substances excreted in the urine was investigated. Practically the whole of the urinary iodine (545 mgm. per diem) was accounted for by the presence of a mixture of 3 : 5-diiodo-4-hydroxy- and, somewhat surprisingly, 3 : 5-diiodo-4-methoxy-benzoic acids in approximately equal proportions.

The acidified urine was extracted with ether, and the ether layer further extracted with sodium hydroxide. Acidification of the alkaline solution precipitated a mixture of iodinated benzoic acids, which, after crystallization from alcohol, melted at 247° (decomp.). This is rather higher than the figure in the literature[2], namely, 237°, for 3 : 5-diiodo-4-hydroxybenzoic acid. The analytical figures (C, 24·4; H, 1·6; I, 62·2 per cent), however, approximated more closely to those for 3 : 5-diiodo-4-methoxybenzoic acid (calc. for $C_8H_6O_3I_2$: C, 23·7; H, 1·5; I, 62·8 per cent) than to those for the hydroxy-acid (calc. for $C_7H_4O_3I_2$: C, 21·5; H, 1·0; I, 65·2 per cent). Repeated recrystallization finally raised the melting point to 261° (decomp.). Wheeler and Liddle[3] report that the methoxy-acid decomposes at 255–256°.

Esterification of the mixed acids with methanol and sulphuric acid gave a mixture of the methyl hydroxy- and methoxy-esters, which were separated by virtue of the solubility of the former in alkali. The methyl 3 : 5-diiodo-4-hydroxybenzoate crystallized from methanol in colourless needles, melting point 168° (in the literature[3], 166–167°) (found: C, 24·2; H, 1·6; I, 62·7; calc. for $C_8H_6O_3I_2$: C, 23·7; H, 1·5; I, 62·8 per cent). A mixed melting point with an authentic sample produced no depression. The methyl 3 : 5-diiodo-4-methoxybenzoate, crystallized similarly, had melting point 95° (in the literature[3], 95°) (found: C, 26·1; H, 1·9; I, 60·6; calc. for $C_9H_8O_3I_2$: C, 25·85; H, 1·9; I, 60·8 per cent). Admixture with an authentic specimen did not depress the melting point.

This work will be discussed more fully elsewhere; but in view of the absence of references in the literature to the methylation of phenolic hydroxyl groups in the animal body (see Lederer[4]), we considered it desirable to place these preliminary results on record.

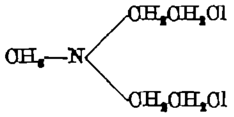
Combination of Nitrogen-15-labelled Nitrogen Mustard with Proteins

The nitrogen mustards readily inactivate certain enzymes[1] and they also react with many other proteins[2], including the components of hæmolytic complement[3]. Although it has been established by various investigators that the amino, sulphydryl, sulphide, carboxyl and pyridine groups of proteins are affected by the action of the nitrogen mustards[4], there appears to be no precise quantitative information about the combination of the mustard with proteins.

We have recently prepared one of the most commonly used nitrogen mustards, methyl *bis*(β-chloroethyl)amine (code No. HN2), labelled with nitrogen-15, and have used this tagged compound (containing 30·4 atoms per cent excess nitrogen-15) to determine the amount of nitrogen mustard which combines firmly with various proteins at *p*H 7·4 and 37°.



Methyl *bis*(β-chloroethyl)amine

Our investigations have shown that considerable amounts of this nitrogen mustard combine firmly with the serum proteins and ovalbumin. The compounds produced contain appreciable amounts of nitrogen-15 even after prolonged dialysis, or precipitation followed by repeated washing with methanol, to remove loosely attached nitrogen mustard and its 'hydrolysis' products (cyclic and other transformation compounds formed by the nitrogen mustards in aqueous solution). The following results of typical experiments with ovalbumin show that the protein treated with nitrogen mustard may contain 3·5

Nitrogen mustard added to 624 mgm. ovalbumin		Molecular ratio* (nitrogen mustard/ovalbumin) in the product	
(Mgm.)	Mol. per mol. of ovalbumin	After dialysis	After precipitation with methyl alcohol
8	2·8	0·5	1·4
12	4·3	1·1	2·4
16	5·7	1·5	3·5

* Assuming a molecular weight of 42,000 for ovalbumin.

nitrogen mustard residues per molecule of ovalbumin, and there is no reason for believing that this is a maximum value.

Part of the nitrogen mustard in the product is apparently not firmly combined with the protein, since it is removed during prolonged dialysis against sodium chloride solution; and this observation is consistent with results we have obtained in immunological studies with proteins treated with nitrogen mustard[5]. These immunological investigations have shown that nitrogen mustard effects a slight but detectable change in the immunological properties of proteins. Thus, the injection of ovalbumin treated with nitrogen mustard into rabbits leads occasionally to the production of antibodies capable of giving slight precipitation of heterologous nitrogen mustard-proteins (for example, horse serum proteins treated with nitrogen mustard). Because of the small amount of precipitate obtained, we have not yet been able to make a complete analysis of it with the heterologous antigen, but precipitates obtained with the labelled homologous antigen have been examined. For example, precipitates obtained with the nitrogen mustard–horse serum protein and nitrogen mustard–ovalbumin antigen–antibody systems contained, respectively, 0·086 and 0·024 atoms per cent excess nitrogen-15. Assuming a nitrogen content of 16 per cent and an arbitrary mean molecular weight of 100,000 for all the proteins, these values correspond to 3·3 and 0·8 nitrogen mustard residues per molecule of total protein (antigen plus antibody).

These results with the serological precipitates, like those with dialysed and methanol-precipitated nitrogen mustard-treated ovalbumin (and serum proteins), show that nitrogen mustard combines firmly with various proteins under physiological conditions of *p*H and temperature.

We are indebted to the Medical Research Council and the British Empire Cancer Campaign for grants which have covered the expenses of this investigation.

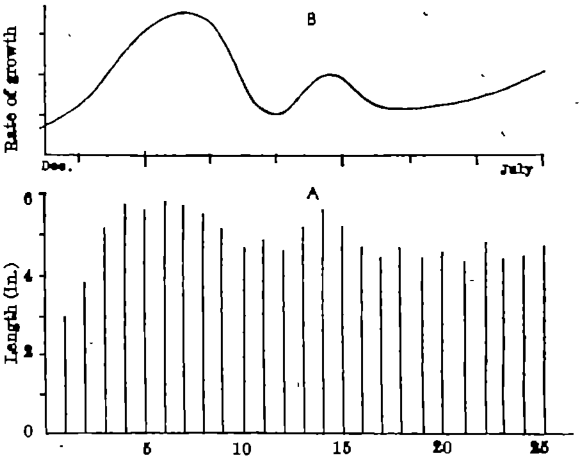
Intraseasonal Growth Variation and Cultivation of Sugar-cane

In my previous work[1,2], I have explained the parabolic growth-variation as noticed in the sizes of the successive leaves, internodes, flowers, fruits and seeds formed from time to time during a season, stressing the importance of this knowledge for the selection of better planting material. The influence of the robustness of seed or planting material on the progeny and yield has been sufficiently stressed by many[3]. I have applied this method successfully to the cultivation of sugar-cane, rice, cotton, mulberry, turmeric and many other plants on an experimental scale, and feel that this could be applied with advantage to the cultivation of most plants.



A, Successive internodes and their lengths; *B*, general growth-curve for the period

The variety of the cane selected was *CO* 419, a hardy variety, introduced into the farms round about Mandya and extensively cultivated. Growth of the cane from time to time was recorded, to have an idea of the growth peculiarities. The accompanying figure is the record of a cane harvested from a standing crop about a year old. It shows the length and number of the successive internodes formed during the several months (*A*) and part of the annual growth-curve (*B*) recorded by me[2]. The agreement is noticed during the earlier period; but this agreement is disturbed as the cane begins to mature, although the growth-vigour of the planting material from this part satisfies the growth-curve of the season. From a standing crop about a year old, canes were harvested and 'setts' were cut from the top and numbered, so that the setts of the same number of all canes might represent the growth region of the same period. These setts, each with three eye-buds, were planted in the experimental plots on October 8, 1947, and the crop of the experimental and the bulk plots was harvested during the last week of November 1948. The method of cultivation for both the plots was the same. The results in the accompanying table will give an idea of the various aspects connected with the different setts.

From these results, it is noticed that on the whole the first two setts are the best for early October planting. The next in order are the third and the fourth. The fifth and the sixth setts are poor because of age, while the other available setts often made

No. of the setts	Average No. of tillers and primaries (after 4 months) per sett	Average No. of canes per sett	Estimated tonnage per acre (approx.)	Percentage of sucrose in juice
I and II	6·1	3·68	38¼	18·96
III and IV	4·7	3·61	36¼	19·22
V and VI	3·3	3·2	31¼	19·01
Bulk	—	3·2	33	19·05

Age of the canes used for cultivation, 1 year approx., date of planting, October 8, 1947; date of harvesting, November 28, 1948, number of selected setts, 456; number of setts for bulk planting, thousands.

use of by the farmers for planting were the poorest, because they were even older. The same order does not hold good for planting during the other months. The figure will explain this point clearly. The method of selection based on this knowledge will denote the following advantages: (1) economy in the planting material; (2) uniformity in the quality of the yield; (3) maintaining and probably improving the vigour of progeny; (4) increasing the yield per acre.

A detailed paper dealing with this subject will be published later on.

I am indebted to the authorities of the Mysore Sugar Co. for giving the necessary facilities for this work in their factory and farms in Mandya.

Effect of Light on the Germination of Watercress Seeds

In obtaining data for the two species of watercress for "Biological Flora" accounts, it was found that, whereas the seeds of *Nasturtium officinale* R.Br. would germinate both in the light and in the dark, those of *N. microphyllum* Boenningh. ex Rchb.[1] would only germinate in the light. This has been checked, as is shown below—there were fifty seeds in each Petri dish and they were kept on moist filter paper at laboratory temperature (about 65° F.).

Table 1

	Light		Dark	
	Percentage germination after		Percentage germination after	
	1 week	2 weeks	1 week	2 weeks
N. officinale	84	86	82	82
N. microphyllum	22	60	0	0
N. microphyllum	12	56	0	0

The amount of light required for the germination of *N. microphyllum* seeds appears to be very small. Thus, in one experiment five minutes light given one day after setting up the dishes produced 4 per cent germination in two weeks, and a second exposure of five minutes light given at the end of this two weeks period produced a further 92 per cent germination in the following two weeks. In another experiment the dishes were given single exposures of five minutes light one, two, three and four days after setting up, and the percentage germinations after two weeks were 8, 36, 60 and 58 respectively, the dark control having 0 per cent and the light control 82 per cent germination.

The effect of light on germination can be either by altering some condition of the testa (for example, in relation to permeability to oxygen) or by bringing about some change in the embryo or endosperm (for example, by catalysing the conversion of reserves into soluble substances). In *N. microphyllum* the endosperm can probably be neglected, since in mature seeds it consists of a single layer of cells only. It also appears that the effect of light is on the embryo and not on the testa, since pricking the testas after the seeds had absorbed water did not lead to any germination in the dark, although the pricked seeds germinated as well as the controls when they were later exposed to light.

Another method of deciding for *N. microphyllum* whether the light acts upon the testa or upon the embryo is to utilize three types of hybrid seeds for experiments. This method will also, of course, give some genetical information. These three types of hybrid seed are (*a*) *N. microphyllum* female × *N. officinale* seeds, which have a hybrid embryo in an *N. microphyllum* testa; (*b*) autotetraploid *N. officinale* female × *N. microphyllum* seeds, which have a hybrid embryo in an *N. officinale* testa; and (*c*) seeds obtained by selfing an amphidiploid produced by colchicine treatment of the hybrid *N. microphyllum* × *officinale*—these seeds have both hybrid testas and hybrid embryos. Results for these three types of seed and for autotetraploid *N. officinale* were:

Table 2

	No. of seeds in each dish	Light Percentage germination after		Dark Percentage germination after	
		1 week	2 weeks	1 week	2 weeks
Autotetraploid *N. officinale*	25	20	32	8	28
N. microphyllum × *N. officinale*	88	53	66	0	0
Auto-4 × *N. off.* × *N. microphyllum*	62	37	77	0	0
Amphidiploid *N. microphyllum-officinale*	27	22	69	0	7

Although the percentage germination of autotetraploid *N. officinale* was rather low, it can be seen that it behaves like *N. officinale* itself. The other results suggest first that the effect of light on germination is via the embryo and not via the testa, and secondly that inability to germinate in the dark is dominant to ability. This second conclusion would be expected, since it has been shown that *N. microphyllum* is an allotetraploid species from *N. officinale* and some other species[2].

Results for the occasional seeds produced by the hybrid *N. microphyllum* × *officinale* support the above conclusions. Such seeds will all have hybrid testas, but a segregation of the two types in their embryos would be expected. In an earlier experiment it was, in fact, found that 5·0 per cent of 121 such seeds germinated in the dark and 31·8 per cent of 164 seeds germinated in the light.

Similar results to those reported above for watercress have been obtained by Honing[3] for *Nicotiana*. He found first that the need of light for germination was dominant to the indifferent condition in which seeds germinate both in darkness and in the light, and secondly that in reciprocal crosses of light-needing and indifferent types the effect could not be due to the testas but must be due to either the embryo or the endosperm.

Organic Acids of the Apple Fruit

It has generally been assumed that the only carboxylic acid present in the fruit of Bramley's Seedling apple is malic acid; but in 1949, when examining chromatograms run in *n*-butanol–formic acid–water (40 : 10 : 50 v/v[1]) of methyl alcohol extracts of pulp tissue of young Bramley's Seedling apples, we noted that several spots having an acid reaction to bromophenol blue appeared on the chromatograms.

In addition to a relatively large spot corresponding with malic acid ($R_F = 0{\cdot}49$), there appeared a second well-defined spot ($R_F = 0{\cdot}18$) and traces of a third spot ($R_F = 0{\cdot}07$). It was possible to wash some of the acid ($R_F = 0{\cdot}18$) from the chromatogram and carry out tests on the solution so obtained. The acid gave a strongly positive citrazinic acid test[2], given also by citric and aconitic acids. The R_F value of the unknown acid was, however, quite different from citric acid (0·40), aconitic acid (0·74) and *iso*citric acid lactone (two spots, 0·64, 0·69, probably due to stereoisomerism).

From the R_F values obtained under carefully controlled conditions at 20° C., the R_M values[3] $\left[\log\left(\frac{1}{R_F}-1\right)\right]$ of the new acid (+ 0·66), citric acid (+ 0·18) and tricarballylic acid (− 0·31) were found to differ by almost equal amounts ($\Delta R_M = 0{\cdot}48$, 0·49) and suggest a stepwise addition of hydroxyl groups to tricarballylic acid. It would appear, therefore, that the new acid might well be a dihydroxy tricarballylic acid.

The acid appeared to decrease in amount as the fruit ripened and also appeared to be present in the pulp of the fruit of peach and plum.

One of us (A. C. H.) has since examined other varieties of English apples for the presence of the new acid. It has been found in much greater quantity in young Worcester Pearmain and young Cox's Orange Pippin apples. In order to study its chemistry, an appreciable amount of the acid has now been obtained from young Worcester Pearmain apples. The fruit was extracted with cold 80 per cent alcohol and the alcohol removed by evaporation. Amino-acids and bases were removed from the resultant aqueous solution by passing it down a column of 'Zeo Karb 215', and the carboxylic acids were absorbed from the filtrate on a column of 'Deacidite E'. Displacement of the acids from this column with 0·1 *N* hydrochloric acid gave several hundred milligrams of the new acid (as the lactone) free from malic acid and chromatographically homogeneous. The chemical characterization of the acid will be described elsewhere.

Formation of Green Pigment in Grasshoppers

The factors which lead to the production of green pigment in grasshoppers are still in doubt. Some authors[1-3] claim that the deposition of green pigment, like that of grey, orange and brown, is determined by the background; others[4-6] have found that the background is without effect. Faure[5] obtained green individuals only when they were fed on growing grass in a humid atmosphere.

Observations carried out in the University of Ankara during 1949 and 1950 support the findings of Faure. Yellow hoppers of *Acrida turrita* were reared in green cages. When fed on growing grass, 69·8 per cent became green; when fed on cut grass changed every other day, 10·9 per cent became green; when fed on dry grass, none became green. If green hoppers were kept in green cages and fed on dried grass, only 21 per cent remained green; whereas if they were fed on growing grass, 78 per cent remained green.

Similar results were obtained with the hæmolymph. The hæmolymph of yellow hoppers collected from dry grassy places is yellowish or colourless, never green. In green hoppers collected from areas of green grass the hæmolymph is green in 90 per cent of them. If the yellow hoppers from the former locality are fed on green grass, the hæmolymph gradually becomes green, and after moulting the integument becomes green. The green pigment thus appears in the blood before it is deposited in the integument.

The green pigment is known to be a combination of a yellow carotene-protein with a blue bile pigment protein[7-9]. The appearance of green individuals depends on the formation of bile pigment. It seems possible that this pigment is derived from the breakdown of chlorophyll and that for some undetermined reason this happens only when the grasshopper feeds on fresh growing grass. It is noteworthy that the excreta contain a large amount of free magnesium in hoppers of both colours.

It is hoped to confirm and extend these results in further laboratory experiments.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer, and an Assistant Lecturer, in the Department of Chemistry—The Clerk, Birkbeck College, Breams Buildings, London, E.C.4 (August 17).

Assistant (female) for field experiments on fruit crops for the Plant Pathology, Entomology and Plant Protective Chemistry Sections—The Secretary, East Malling Research Station, East Malling, Maidstone, Kent (August 18).

Assistant, Grade B (graduate, preferably with some knowledge of a branch of applied chemistry or of geology) in the Department of Chemistry, a Lecturer in Physics, and an Assistant Teacher of Microbiology, Nutrition and Food Analysis in the Department of Bakery and Catering—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (August 18).

Scientific Officer (with first- or second-class honours degree in mechanical engineering) for research and development work on mechanical engineering problems (Ref. R/A); a Senior Scientific Officer (with first- or second-class honours degree in mechanical engineering and at least five years experience in industry and/or research and development work) for development to prototype stage of mechanical mechanisms of an original nature (Ref. R/C.1); a Scientific Officer (with first- or second-class honours degree in mechanical engineering and two to three years industrial and/or research experience) for work on combustion and heat transfer problems (Ref. R/C.2); an Experimental Officer (with pass degree or equivalent and at least four years experience in industry and/or research) with experience in electrical instrument design and electronics control and supervisory equipment (Ref. R/C.3); a Senior Scientific Officer (with first-class degree in agriculture, or first- or second-class honours degree in natural science with postgraduate diploma in agriculture) for department carrying out impartial tests of the performance of agricultural and horticultural machinery under practical conditions (Ref. A/T.1); and a Scientific Officer (with first- or second-class honours degree in mechanical engineering, and two to three years industrial experience desirable) to work on engineering problems arising during impartial tests of the performance of agricultural and horticultural machinery under practical conditions, and to develop special testing apparatus (Ref. A/T.2)—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds. (August 18).

Lecturers (Grade I and Grade II) in the Department of Chemical Engineering—The Secretary, The University, Birmingham 3 (August 20).

Scientific Technologist, Grade I (with a good general training in chemistry, preferably up to degree standard) at the Coal Survey Laboratory in Nottingham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting CT/360 (August 20).

Assistant (Grade B) to teach Geography for Inter.B.Sc., and an Assistant (Grade B) to teach Mathematics for Inter.B.Sc., O.N.C. mechanical engineering, and also Final B.Sc. and H.N.C., at the Luton and South Bedfordshire College of Further Education—The Borough Education Officer, Education Office, 63–69 Guildford Street, Luton, Beds. (August 25).

Assistant Physicist (with an honours degree in physics) to the Radiotherapy and X-Ray Diagnostic Departments—The Personnel Officer, St. Thomas's Hospital, London, S.E.1 (August 25).

Operational Research posts in the Field Investigation Group of the Directorate of Scientific Control (candidates should have a good honours degree, or equivalent, in science, mathematics or engineering)—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed 22/361 (August 25).

Tutorial Studentship in Mathematics—The Registrar, King's College, Strand, London, W.C.2 (August 25).

Assistant Lecturer in Agricultural Botany, and an Assistant Lecturer in Agricultural Chemistry (Dairy Chemistry)—The Registrar, The University, Reading (August 27).

Assistant Lecturer in Physics—The Registrar, The University, Leeds 2 (August 27).

Deputy Mechanical Engineer—The Clerk of the Metropolitan Water Board, New River Head, Rosebery Avenue, London, E.C.1, quoting Ref. (T) (August 29).

District (Forest) Officers to the Forestry Commission (with university degree in forestry, a university diploma in forestry, or a postgraduate degree in a forestry subject)—The Secretary, Civil Service Commission, 6 Burlington Gardens, London, W.1, quoting No. 146/51 (August 30).

Lecturer (Grade II) in Coal Preparation—The Secretary, The University, Edmund Street, Birmingham 3 (August 30).

Research Fellow (with the degree of Ph.D., and good experience in research in organic chemistry) to act as leader of a team engaged upon research in the Chemical Constitution of Coal, and a Research Assistant (with a good honours degree in chemistry) in Coal Constitution—The Secretary, The University, Edmund Street, Birmingham 3 (August 30).

Assistant in the Department of Moral Philosophy—The Secretary, The University, Old College, South Bridge, Edinburgh (August 31).

Assistant Lecturer in Botany—The Registrar, University College, Cathays Park, Cardiff (August 31).

Food Technologist in the Department of Health, Southern Rhodesia—The Secretary to the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (August 31).

Lecturer in Animal Husbandry—The Registrar and Secretary, The University, Bristol (August 31).

Lecturer (with good qualifications in Chemistry and prepared to specialize on problems connected with the physico-chemical structure of collagen, the chemistry of collagen, or the chemistry of the vegetable tannins), an Assistant Lecturer or Lecturer (with practical experience in Leather Manufacture, especially in leather dyeing and finishing, and able to take charge of an experimental tannery), and a Research Assistant (with a good honours degree in Leather Chemistry, Chemistry, Biochemistry, or Bacteriology with, preferably, some research experience) in the Procter International Laboratory—The Registrar, The University, Leeds 2 (August 31).

Scientific Officers (with a first- or second-class honours degree or equivalent in physics, electrical engineering, mathematics, mechanical or aeronautical engineering, and capable of undertaking research or development work in general physical problems, electronics, aerodynamics, instrumentation or light mechanisms) at the Royal Aircraft Establishment, Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.212/51A (August 31).

Lecturer in Bacteriology in the Department of Pathology, University College of the West Indies—The Secretary, Senate Committee on Higher Education in the Colonies, Senate House, University of London, London, W.C.1 (September 1).

Plant Physiologist in the Department of Botany, for work with radio-active isotopes—The Registrar, The University, Leeds 2 (September 1).

Senior Lecturer or Reader in the Chemistry of High Polymers in the Department of Textile Industries—The Registrar, The University, Leeds 2 (September 1).

Assistant Lecturers (2, with qualifications in either the microbiology of dairying, or the biochemistry of micro-organisms) in the Department of Microbiology—The Registrar, The University, Reading (September 3).

Assistant Lecturer (honours graduate in chemistry or metallurgy with special interests in physical chemistry) in Metallurgy—The Registrar, The University, Manchester 13 (September 4).

Readership in Pathology at the Institute of Ophthalmology—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 5).

Chemist I by the Ministry of Supply in London, for the investigation and assessment of requirements of non-metallic materials for aircraft and associated production, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.544/51A (September 8).

Chemist II or Chemist III (Metallurgist) at a Ministry of Supply establishment in Lancashire, to assist the Chief Metallurgist in the control of laboratories dealing with development work, experimental heat-treatment problems, and production of electric steel and steel heat-treatment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.543/51A (September 8).

Chemist III/Engineer III by the Ministry of Supply in London, for the investigation of requirements for materials used in aircraft production, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.545/51A (September 8).

Lecturer in Chemical Engineering at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 8).

Entomologists (with a degree in zoology and a sound knowledge of entomology and botany) to carry out a survey of the tsetse areas of the Sudan and undertake research work—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Entomologist' (September 15).

Lecturer in Child Psychiatry—The Registrar, The University, Manchester 13 (September 15).

Lecturer in Mineral Dressing and Assaying in the Department of Chemical Engineering, University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 15).

Lecturer in Physiology—The Secretary of University Court, The University, Glasgow (September 15).

Chair of Zoology—The Secretary, The University, Edmund Street, Birmingham 3 (September 17).

Electrical Engineers and Physicists (Senior Scientific Officer grade) (with a first- or second-class honours degree in the appropriate subject, at least three years postgraduate research experience, and a wide knowledge of communications work and H.F., V.H.F. or display techniques for research work associated with design and development of airborne and ground equipments) at the Royal Aircraft Establishment, Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.159/51A (September 22).

Mathematicians, Mechanical and Aeronautical Engineers at Ministry of Supply headquarters in London: Senior Scientific Officer (Ref. C.441/51A) for administration of bomber aircraft research and development, Scientific Officer (Ref. C.442/51A) for co-ordinating aerodynamic research work in the Ministry and of research projects at aircraft firms, and a Scientific Officer (Ref. C.422/51A) for performance assessment of fighter aircraft in connexion with industrial firms' projects—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 22).

Physicists and Mathematicians at a Ministry of Supply experimental establishment in Essex, for work connected with out-of-door instrumentation: Physicist (Senior Scientific Officer grade) with some mathematical knowledge including statistics or a Statistician with some interest in experimental procedure to be in charge of a team investigating the performance of weapons, Physicists (Scientific Officer grade) preferably with some knowledge of experimental range technique and procedure, Experimental Physicist (Scientific Officer grade) with experience of metallurgical techniques, and a Mathematician (Scientific Officer grade) with interest in experimental methods and some knowledge of hydrodynamics—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.220/51A (September 24).

Chair of Mathematics at Victoria University College, Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 1).

Senior Lecturer in the Department of Civil Engineering, University of Natal—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

TUBE INVESTMENTS RESEARCH FELLOWSHIP in the Department of Engineering Production—The Secretary, The University, Edmund Street, Birmingham 3 (October 31).

DIRECTOR OF THE DEPARTMENT OF AGRICULTURE, STOCK AND FISHERIES, Territory of Papua and New Guinea—The Secretary, Department of Territories, Canberra, A.C.T., Australia (December 31).

ASSISTANT LECTURER IN PHYSICS—The Registrar, The University, Nottingham.

CIVIL ENGINEER in the Department of Works and Hydraulics, Trinidad—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27322/74.

DISTRICT ENGINEER in the Public Works Department, Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, quoting 'District Engineer 4/19 S.T.'.

IRRIGATION ENGINEERS under the Government of Nigeria—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27322/154.

JUNIOR RESEARCH OFFICER (male, with honours degree in chemistry or equivalent) for analytical work, including research on the development of new methods and application of existing methods for special purposes—The Director, British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester 20.

LECTURER IN FOOD SCIENCE in the Department of Bakery and Confectionery—The Principal, Borough Polytechnic, Borough Road, London, S.E.1.

LECTURER IN THE DEPARTMENT OF MATHEMATICS AND MECHANICS, capable of taking pure and applied mathematics up to final honours standard—Prof. H. Levy, Imperial College of Science and Technology, South Kensington, London, S.W.7.

PHYSICISTS (with a first- or second-class honours degree in physics, or equivalent qualification) to supervise and undertake research work involving the application of physical methods to the study of metals and the control of new metallurgical processes—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

PRINCIPAL METALLURGIST to take charge of a laboratory engaged on research into powder metallurgical techniques of rare metals, SENIOR METALLURGISTS to supervise groups engaged on powder metallurgical research, and METALLURGISTS to undertake research work on the powder metallurgy of rare metals, in the Research and Development Branch, Risley—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, stating post applied for.

RESEARCH DEMONSTRATOR IN MATHEMATICS—The Registrar, University College, Exeter.

SENIOR ELECTRICAL ENGINEER in the Public Works Department, Sierra Leone—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27326/47.

TECHNICAL ENGINEER to undertake fundamental technical work in the application of engineering principles to the design of nuclear reactors and allied atomic energy projects, and to predict the performance of such plants—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

TELECOMMUNICATIONS ENGINEERS and PHYSICISTS (Principal Scientific Officer or Senior Scientific Officer grade) (with a first- or second-class honours degree in physics or telecommunications and upwards of five years experience of research and development in R.F. techniques at centimetric wave-lengths, centimetric radar (preferably for airborne application), servo mechanisms or telecommunication networks and feedback amplifiers) at the Royal Aircraft Establishment, Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.158/51A.

BIOLOGY IN EDUCATION

THE recent issue of *The Advancement of Science*[1] contains the interim report of a special committee which, brief though it is, reveals a disturbing situation demanding the attention of all who are concerned in one way or another with the biological sciences. The committee was set up by the British Association to consider the position of biology and rural science in the school curriculum and matters relating thereto. The material contained in its interim report is the result of questionnaires sent to university departments of education and teachers' training colleges.

Among other findings the committee reports that in secondary modern schools biological work varies from total neglect to a few very good courses based on gardening, etc.; and that in these schools there is a grave shortage of keen, well-qualified teachers. Laboratory work is neglected. In the secondary grammar schools it finds again a serious shortage of well-qualified teachers, though the number with general degrees, or no degree, who teach the subject is increasing. If general science is offered, it is almost always in the hands of non-biologists, and biology is omitted. Out of forty-nine teachers' training colleges from which replies have so far been received, nineteen offer no courses in biology; and including all colleges together, only about 10 per cent of the entrants take biology. Both the quality and quantity of biology entrants are falling off. There is also evidence that students avoid biology since too academic a school training has prevented development of interest in the subject.

The committee does not consider that, in general, any serious hindrance is being presented to the teaching of biology through the lack of suitable laboratory accommodation. On the other hand, it finds that there is gross neglect of work with living organisms and almost total neglect of field-work. In the grammar schools, particularly, courses in biology are too academic and bookish.

To remedy this state of affairs it is felt by the committee that the vicious circle of the too academic approach must be broken in the universities, and that this can be done by much greater stress on field-work. The greater emphasis on the teaching of practical ecology, now apparent in the universities, is therefore, it considers, to be welcomed.

These findings, tentative and incomplete as they are, are in agreement with the experience of others who are familiar with biology teaching in the schools; and had the committee extended its inquiries to private preparatory and public schools it would have been able to confirm that while at sixth-form level some excellent courses in biology are now being offered, often accompanied by good work in the laboratory, and occasionally by well-planned field studies, not much biology is being taught to the younger pupils, and it is still a common experience for a large proportion of the more promising pupils to go up on the classical or literary side.

These facts lead us to the realization that in Great Britain at the present day, in comparison wit subjects as history and literature, and even chemistry and physics, biology is playing a minor part in education. Whether at primary or secondary level, and whether in State or private institutions, as well as in the teachers' training colleges, many children and students take no regular courses in the subject at all. To others it is looked upon as a 'soft option', or as necessary preliminary training for some career. As a whole, such courses in the science of life as are offered are not felt by parents, students and teachers of other subjects to be of such significance as to induce any but a small minority of the more gifted pupils to take it up. To complete the picture, it needs to be stated that during recent months more than one biologist of considerable experience has publicly admitted that he can see no special educational value in biology.

Besides constituting a question of extreme educational importance, this state of affairs is an anthropological situation of absorbing interest.

The committee set up by the British Association is a fact-finding body; only indirectly, in emphasizing the need for more field-work and ecological studies, were its members concerned with motives. They assume that a direct association of interest exists between school and university teaching in biology. In doing this the committee is adopting a relatively narrow concept of biology as an educational medium; one, however, which is widely held by most members of the public as well as by a large proportion of biologists, and which is fostered by the departmental basis on which studies in the life sciences are pursued at the universities.

At school-level, biological studies spring from two main sources. One of these is nature study, a subject suitable for pupils of any age but which appeals only to a certain number of boys and girls, sometimes for psychological reasons. Because of this it is best looked upon as a personal hobby to be pursued chiefly as a voluntary activity. On the other hand, nature study of a more serious kind provides valuable basic training for the specialized courses which follow later at school, and which may be continued at the university.

The other source is to be found in health education. In times past much interest and effort have been put into the teaching of hygiene; but, perhaps because in this case no close link exists between school and university, the subject has failed to keep pace with the advance of medical science; its educational mission has tended to lose impetus and its popularity has waned. Hygiene, as such, is not now often found as a regular subject in the grammar schools, although, as the committee notes, it is retaining a place in the secondary modern schools, sometimes with biology as an adjunct. In making this observation the committee seems to imply that there is a distinction at school-level between biology and hygiene; that is, between biology and biological science.

In the minds of a small but growing number of teachers, such a distinction ought not to be made; the two subjects should be fused together, particularly since in any one school they are usually taught by the same member of the staff. To them it seems that while simple, utilitarian reasons for the inclusion of hygiene in the curriculum for all children are irrefutable, biology, even in the narrowest sense, should also be taught as an essential element in the comprehension of man's place in the universe. They find support for their views coming from individuals and groups of people concerned with social welfare who have been putting forward with increasing insistence demands that the schools should do more than at present in helping to solve problems of moral behaviour, juvenile delinquency, relations between the sexes, marriage breakdown, or those presented by other related social questions.

To requests of this nature, teachers have made varying responses, and a new conception of the educational mission of biology has begun to take shape, which has come to be called social biology. In this respect, it is significant to note that teachers of geography, history, and at a higher level, of economics, are also beginning to feel that greater emphasis should be placed on the social aspects of their work.

The conception of social biology is the product of no single mind or organization. It has, however, been developed farthest by the British Social Biology Council, and brought most consistently before the public through the Council's journal, *Biology and Human Affairs*. Social biology differs from biology as usually accepted in bringing man into the centre of the sphere of interest, and seeking to advance not merely his material welfare but also the whole of his culture through application of the biological sciences wherever opportunity occurs. Apart from the desire to endow biological studies with some social purpose, subject to modification in the light of further research, at no stage has any attempt been made, in Great Britain, to inject into social biology some particular bias or philosophy; its foundations remain strictly scientific. It is merely that a conscious basis has been chosen for these studies in place of the unconscious social situation which served in the past.

Social biology is also in line with what on wider considerations should be the object of all forms of science in education. Clearly, all science should be presented as one single unity, an outlook and a body of knowledge arrived at through the application of scientific method. The links between physics, chemistry and biology need to be strengthened; at the same time, all biological studies should be included, whether they relate particularly to botany, zoology, agriculture, medicine, genetics or physiology. In addition, contacts should be established with psychology and anthropology so as to embrace the other major life sciences, too.

It may be thought to be a stupendous and impossible task for any teacher to undertake to present a balanced conception of all the life sciences; yet with longer traditions behind them similar tasks are willingly shouldered by teachers of history, literature and physics. The task would be impossible at university-level; but it becomes much easier and simpler when it is realized that the school teacher is dealing with ordinary children and that a primary educational requirement is not to leave them with mental indigestion but with minds alert to the continuing progress of science and ready to develop further understanding as they become adult. Viewed in this light, the teaching of social biology becomes a definite obligation which ought not to be shirked. It is one which is being gradually accepted by a growing number of teachers, who, however, find their difficulties increased by their relative isolation and by the varied nature of the departments, institutions and publications from which they have to draw their material.

The movement towards social biology in the schools calls for a similar movement in the universities, where at the present time departmental specialization may foster sectional efficiency but at grave risk of failure to visualize the greater whole. Yet just as the educational process extends from the cradle to the grave, lines of interest should run all the way down from the research worker to those stock figures, the man in the street and the woman in the home. Only with this wider vision does it become clear that in human progress science is fundamental, and that there can be no genuine progress without the understanding that studies of living matter alone can provide; for many of the problems that beset the world to-day, whether personal, social, communal or international, social, moral or spiritual, are essentially biological. It is a vision of this nature that is required to fire the imagination of a larger proportion of the more gifted minds among us; for these minds, particularly, need to have the ideals of truth, goodness and beauty presented to them in forms which are directly applicable in human life and associated with the main interests and strivings of humanity. Such a vision would accord to biology in the schools the status it now so sadly lacks, while at the same time solving the related problems of the poor supply, and frequently meagre attainments, of those who study and teach the subject.

THE BEGINNING OF THE UNIVERSE

The Primeval Atom

An Essay on Cosmogony. By Canon Georges Lemaître. Translated by Betty H. and Serge A. Korff. Pp. ix+186. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1950.) 22*s*. 6*d*. net.

L'Univers

Par Canon Georges Lemaître. Pp. 73. (Louvain: E. Nauwelaerts, 1950.) n.p.

CANON LEMAÎTRE is well known among relativists as one who has made fundamental contributions to the theory of the expanding universe. Soon after his first work on the expanding universe, he advanced the hypothesis that the matter in the universe originally formed a giant atom, from which the atoms at present existing were produced by progressive fission. In "The Primeval Atom", the reasons which led him to this hypothesis are set out in detail. The book, which is the translation of one which appeared in French in 1946, is based on lectures and articles dated between 1929 and 1945, and intended for non-specialists.

The first lecture (1929) introduces the finite but unbounded space of relativity, and suggests that space is expanding. The second (1931) discusses the expansion of the universe in detail and then, extrapolating backward, infers that the universe began in a dense 'atom'. The third lecture (1934) considers the formation of stars and galaxies at the birth of the universe, and suggests that most stars have evolved very little since their formation. The fourth (1945) relates the concept of the primeval atom to the cosmogonic hypotheses of Buffon, Kant and Laplace. The fifth and last (also 1945) runs over the whole range of ideas covered before. In addition to these sections, there is a short mathematical appendix, a preface by Prof. F. Gonseth considering the philosophical aspects, and a foreword by Prof. H. N. Russell, specially written for the English edition.

The earlier sections are as originally written, and have not been modified in accordance with later developments. This has both advantages and disadvantages. The advantages are in giving a more vivid picture of the progress made; the disadvantages, in a certain amount of repetition. As Lemaître says, all the ideas are actually present in the last section, though this would be found too concise by most readers not prepared by reading the earlier sections.

The book certainly is a clear, vivid and fascinating account of the author's own ideas; however, it makes no reference to the divergent views of others. When the first sections were written, the author's hypothesis stood almost alone; now alternative suggestions are being vigorously examined. Lemaître infers the primeval atom by extrapolating backward from the expansion of the universe, from the progressive degradation of energy into increasing numbers of lower-energy quanta, and the progressive increase in numbers of atoms by radioactive fission. But extrapolation over such large ranges of time is notoriously unreliable. Expansion may be only an illusion; it may be characteristic of only part of the universe; or (as in the continuous creation hypothesis) it need not lead back to a dense state. Degradation of energy, though characteristic of laboratory experiments, need not apply to the universe as a whole; and present ideas suggest a progressive decrease in numbers of atoms (by the conversion of hydrogen into helium) rather than an increase by radioactive fission. Again, Lemaître quotes the existence of cosmic rays in support of his ideas; they are the relics of the display of fireworks which attended the birth of the universe. But at present it is regarded as not impossible that cosmic rays are not present everywhere in space, but are confined to the neighbourhood of the sun, or to some region of the Milky Way; and their generation by ordinary electromagnetic processes is being considered, not without prospects of success. Finally, in the light of developments of atomic theory, it is not clear what significance can be attached to the idea of an atom containing all the mass of the universe.

For all these reasons the picture presented by Lemaître must be regarded as only one of the possible pictures. Nevertheless, it is valuable to have this picture. It represents one extreme of the possible cosmogonic hypotheses—the extreme in which the beginning of the universe was as unlike the present and the future as is possible. Such an extreme provides a comparison for assessing later hypotheses.

The translation does not seem to be wholly correct; "une trentaine" and "une trentième" seem to have been confused on p. 32, and there is more than one bad sentence on p. 49. But the difficult points are few. The translators have set out to represent as closely as possible the author's outlook, rather than to translate the words literally; and on the whole they have succeeded.

"L'Univers" is a published version of a series of broadcast talks given by Canon Lemaître in 1950. It gives a popular account of the ideas described in more detail in "The Primeval Atom".

MEASURE AND MEASURABLE FUNCTIONS

Measure Theory

By Prof. Paul R. Halmos. (University Series in Higher Mathematics.) Pp. xi+304. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1950.) 45*s*. net.

THE theory of measure is an essential part of modern analysis, and an up-to-date treatment of it in the English language is very welcome. Prof. P. R. Halmos states that his purpose is to provide a book that should be found usable both as a text for students and as a source of reference for the more advanced mathematician. In my opinion, the advanced mathematician will find the work more useful than the student, who may be discouraged by the somewhat surprising arrangement of its contents. The preface says that "The only necessary prerequisite for an intelligent reading of the first seven chapters is what is known in the United States as undergraduate algebra and analysis. For the convenience of the reader, §0 is devoted to a detailed listing of exactly what knowledge is assumed in the various chapters. The beginner should be warned that some of the words and symbols in the latter part of §0 are defined only later, in the first seven chapters of the text, and that, accordingly, he should not be discouraged if, on first reading of §0, he finds that he does not have the prerequisites for reading the prerequisites." In fact, pp. 3–8 may well terrify the beginner, and are not needed until the last three chapters of the book are reached. If the young student omits these, he may yet be puzzled by the first sentence of chapter 1 (p. 9): "Throughout this book, whenever the word *set* is used, it will be interpreted to mean a subset of a given set, which, unless it is assigned a different symbol in a special context, will be denoted by X".

After this the book becomes more lucid, and the first seven chapters give a good account of sets and classes, measures and outer measures, extension of measures, measurable functions, integration, general set functions, and product spaces. There are many examples which are not as useful as they might have been. The author himself says (p. vi): "It might appear inconsistent that, in the text, many elementary notions are treated in great detail, while, in the exercises, some quite refined and profound matters (topological spaces, transfinite numbers, Banach spaces, etc.) are assumed to be known. The material is arranged, however, so that when a beginning student comes to an exercise which uses terms not defined in this book, he may simply omit it without loss of continuity."

Chapters 8 and 9 are rather more difficult: the former, on transformations and functions, uses the concepts of metric space, completeness, separability and uniform continuity of functions on such spaces; the latter, on probability, includes some important theorems due to Kolmogoroff. This chapter is rather outside the main stream of the argument represented by the rest of the book.

There is a great increase in difficulty in chapters 10–12, in which systematic use is made of many of the results of topology and topological group theory. These are enumerated in pp. 3–8, to which I have already referred. Chapter 10 deals with locally compact spaces, chapter 11 with Haar measure, and chapter 12 with measure and topology in groups. The book concludes with a bibliography and a list of references to it appropriate to different passages of the text, a list of frequently used symbols, and an index.

The book has many merits, and one hopes it will reach a second edition so that the author can remove the unnecessary difficulties in the first few pages, which may conceal these merits from a timid beginner.

H. T. H. Piaggio

LIFE IN THE GRAN CHACO

A Naturalist in the Gran Chaco

By Sir John Graham Kerr. Pp. xiii+235+24 plates. (Cambridge: At the University Press, 1950.) 21*s*. net.

THERE is a rich tradition of naturalist travellers in the University of Edinburgh, dating from the days of James Bruce and Mungo Park in the eighteenth century, and this record of Sir John Graham Kerr's work in the Gran Chaco of South America places him worthily in their distinguished company. It is only from this account, with its day-to-day records and connecting narrative, that one can picture, half a century and more after the events took place, the foresight and planning skill, the endurance, persistence and enthusiasm which brought to successful conclusions two expeditions to a region then practically a scientific blank.

The whole story hangs by a thread—on a bleak afternoon in February 1889 an Edinburgh medical student picks up a copy of *Nature* at the bookstall in Waverley Station, sees a note about a projected Argentine expedition to certain high tributaries of the Rio de la Plata, and so the adventure is conceived and Graham Kerr's scientific future potentially fashioned. As naturalist on Captain Juan Page's expedition, the author penetrated the Gran Chaco, and his observations, made during 1889–91, form the greater part of the book. The second part describes the Lepidosiren Expedition in the same region, undertaken with John Budgett during 1896–97.

The aims of the two journeys were different in kind: the second had a definite objective, the elucidation of the habits and early development of the American lung-fish, about which nothing was known; but that does not preclude supplementary descriptions of other notable inhabitants of the swamps. Vividly the narrative recounts the difficulties and early disappointments encountered and surmounted; and most naturalists to-day are familiar with the value of the direct results, embryological and evolutionary, which followed from the observations and collections then made in the marshes of Paraguay.

The first journey was of another sort: it was a naturalist's roving commission, and every observation in this unobserved country came as grist to the young and enthusiastic traveller. The final and mysterious disappearance of his collections after he had left the river-steamer *Bolivia* was a serious but not a crippling loss, for the vital contributions to knowledge were the field observations recorded in this book. They include a comprehensive account of the Chaco fauna in the neighbourhood of Fortin Page; but more revealing are the innumerable notes on habits, on obliterative coloration, which in its manifold aspects clearly made a deep impression on the author, on the adaptations of the animal inhabitants of the swamps, and, most striking of all, on the characteristics of the human inhabitants, an outlying and restricted branch of the redskin Tobas, the Natokoi.

These wandering and marauding people, without huts or tents or domestic animals except the dog, unable to count above seven, recognizing the moon's phases but with no idea of the number of days in a month, depending on wooden weapons, though their bows had back-strings and their arrows were feathered to rotate, represented at its simplest a primitive hunter–fisherman stage of culture. The account of their daily routine, their simple industries and social customs makes a fascinating tale which could have been revealed only to one received into the bosom of the tribe.

The author has done well in resuscitating these old diaries, so that others may share in the observations and stimulation of his Gran Chaco adventures, which long since have borne rich scientific fruit.

James Ritchie

TAXONOMY OF *PENICILLIUM*

A Manual of the Penicillia

By Kenneth B. Raper and Charles Thom. Pp. ix+875+10 plates. (London: Baillière, Tindall and Cox, 1949.) 91*s*. 6*d*.

Species of the genus *Penicillium* are of common occurrence, wide distribution, and considerable economic importance. Naturally the taxonomy of the genus has received much attention, in spite of its great difficulty. Thom himself has been studying *Penicillia* for half a century, during which time he has gradually brought order out of chaos. His monograph of 1930, though unsatisfactory in some details, laid down broad lines of classification which have stood the test of time. It is a tribute to the soundness of his work that most of the new species described by others during the intervening years are accepted by Raper and Thom in their new manual.

The book is arranged on much the same plan as the earlier "Manual of the Aspergilli" (1945), with three main sections: general discussion, the manual proper, and reference material. Although it is expressly stated that the manual is not a monograph, the first two chapters include a fairly comprehensive account of the history of the genus and synonymy. Chapter 3, "Observation and Description of Penicillia", deals fully with the morphological characters on which classification is based. Then follows a chapter on methods of cultivation and preservation of cultures, and the section concludes with a brief but useful account of the production of penicillin, the stress naturally being on the purely mycological aspects.

The second section of the book begins with a chapter on the use of the manual, and includes two keys to the main groups and series. The succeeding eight chapters deal respectively with the main groups within the genus, and the section concludes with a chapter on the three related genera, *Gliocladium*, *Paecilomyces* and *Scopulariopsis*. Each chapter includes a key, or keys, to the series and individual species; full diagnoses, including descriptions of colonies on three different culture media; discussion of synonymy; and a section on occurrence and distribution, which not only gives a picture of the ubiquity of these organisms, but also provides a useful fund of information on their biochemical characteristics. There are numerous illustrations from photographs of colonies, and photomicrographs and drawings of typical fruiting organs, also ten plates in colour.

The final section of the book comprises a topical bibliography, covering most of the literature on systematics and activities of *Penicillia*; a general bibliography; check list of species and genera, accounting for all names which have been applied to *Penicillia*, and other names which are synonyms of *Penicillium* and the three related genera; and finally a list of accepted species.

The "Manual" is a magnificent piece of work, deserving of the highest praise. Everything has been done to aid the student of the genus and to simplify identifications. Thom's conception of 'group species'—fundamentally the recognition that, in any species of living organism, no two individuals are identical—has been extended to cover the majority of the 137 species recognized. In addition, closely related species are grouped into 'series', the results of this classification being embodied in a diagrammatic key (p. 120) which makes the approximate identification of any isolate a comparatively simple matter. Another excellent feature is the direct comparison of the various species belonging to a single series. Anyone familiar with Thom's monograph will notice that a number of species have now been transferred to different series or groups. In all such cases the new classification makes for a more rational grouping, and will facilitate identifications.

A few minor points require criticism. The term 'phialides' is not of Latin origin, and the singular is not 'phialis' (p. 45). The antibacterial spectrum test, as an aid to confirming identifications of some species, is useful, but no mention is made of testing culture fluids with ferric chloride, a test which is simpler to carry out and which has a wider application. Few mycologists would agree with the statement that the chlamydospores (or aleuriospores) produced by *Paecilomyces varioti* have any connexion with ascus formation in *Byssochlamys fulva*. The topical bibliography, a most useful adjunct to the taxonomic sections, is unfortunately marred by many orthographic errors, chiefly in the German titles of papers. These, however, are small blemishes in a first-class book, which is likely to remain the standard treatise on *Penicillium* for many years to come.

The format of the book maintains the high standard set by the earlier "Manual of the Aspergilli", and the text is commendably free from misprints. In spite of its somewhat high price the book should, and undoubtedly will, become an indispensable part of the equipment of every serious student of moulds.

G. Smith

Medical Botany

A Hand-book for Medical Men and All who are Concerned in the Use of Plants; Nutritionists, Dieticians, Pharmacists and Veterinarians. By Dr. Alexander Nelson. Pp. xi+544+16 plates. (Edinburgh: E. and S. Livingstone, Ltd., 1951.) 30*s*. net.

THIS book sets out to give an account of the uses to which plants can be put by man as food and drugs and also of those plants which directly cause disease or injury to man.

The field covered is very wide and thus the amount of information which can be conveyed under any one heading is rather small. This results in the book being too generalized for the serious student of dietetics or nutrition or pharmacology and not elementary enough for the "members of the general public" mentioned in the introduction.

The most serious criticism of this book which can be offered is that the information contained is thrown together without any attempt at a critical assessment on the part of the author. This, together with a somewhat unkind use of the English language, makes recommendation impossible.

Two quotations must suffice to illustrate these points. On p. 209, in the section on the broad bean, occurs the following sentence: "Apart from the use of garden beans in the young state, these seeds are used, almost exclusively, for stock food. A bean feast was not a feast of beans—the name has quite a different origin." (But we are not told what this different origin is, which is a pity; though authorities do not seem clear about it. The term may have originated from the custom of having a feast on Twelfth Night when a cake with a bean buried in it was cut; the person who received the slice containing the bean was elected 'bean-king'.)

Again, from p. 464 comes the following: "The probability of addiction following the use of opium and its derivatives has led to an increasing degree of control being exercised by governments on the growth of the poppy and the subsequent handling of the drug." Which sentence, taken at its face value, means that government controls must be added to the factors limiting plant growth.

Finally, not all will applaud the classification of alcohol as a food while tea is considered as a drug.

G. E. H. Foxon

Giordano Bruno

His Life and Thought. With annotated translation of his work, On the Infinite Universe and Worlds. By Dorothea Waley Singer. Pp. xi+389+9 plates. (New York: Henry Schuman; London: Constable and Co., Ltd., 1950.) 40*s*. net.

GIORDANO BRUNO the Nolan (1548 ?–1600) presents us with a problem of exceptional interest both for philosophers and historians of science. Scarcely less important is the place which he occupies in the development of ecclesiastical politics. As a personality, too, he is without rival among extreme psychological types, conditioned by a series of complex events. It is impossible to read this book without an intense sympathy for this "martyr of science", notwithstanding his infuriating follies.

Bruno's philosophy is essentially that of "an infinite universe with an infinity of worlds". Several consequences follow, of which his formulation at least cannot be regarded as particularly original. His role was more that of a seer. But, oddly enough, his cosmology stemmed from two opposing roots, namely, those of Lucretius and of Cusanus. The former's thought was fundamentally mundane, the latter's subservient to his theology.

As the theme unfolds, we see something of Bruno's couple of years in Elizabethan London, of his rare periods of comparative repose, and of the gathering storm, culminating at the stake. Of special value is the annotated translation of his "On the Infinite Universe and Worlds". Like his great contemporaries, the humanist architects, Bruno found fascination in numbers, and in a certain species of transcendence.

Mrs. Singer has performed a great task—her erudition and restraint make the living and dying of her fulminating hero a stern reality in this twentieth century.

F. I. G. Rawlins

Synthetische Methoden der organischen Chemie

Von W. Theilheimer. Repertorium 3. Pp. viii+412. (Basel and New York: S. Karger, 1949.) 40 Swiss francs.

THIS volume is the third of a series devoted to an attempt at the systematic recording of new synthetic methods in organic chemistry. Such a classification involves inherent difficulties which the author overcomes by the introduction of a novel system of reaction symbols representing processes such as addition, elimination, rearrangement and exchange, which are used in conjunction with a few empirical rules. For the casual reader who may have neither the time, nor perhaps the inclination, to master this new technique, there is an alphabetical subject index which covers the first three volumes.

It is not clear on what basis the selection of material is based. It is sometimes difficult to decide with certainty whether a reaction is in fact new, and even more difficult to decide whether a given method is an improvement on a known process or not. In these circumstances, the selection of the subject-matter must become largely a matter of personal experience and opinion. The present volume refers mainly to publications of 1946 and 1947 and contains a high percentage of references to work published in the United States, which is intended to compensate in some measure for the paucity of American references in Vol. 2.

The volumes in this series are likely to be of some value to research workers and others engaged in preparative organic chemistry, in that they provide that type of information which might otherwise be difficult to locate. The inclusion of the "English Index Key" grossly underrates the intelligence of the average English-speaking reader.

Advanced Organic Chemistry

By Prof. Reynold C. Fuson. Pp. x+669. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 64*s*. net.

THIS book departs from the usual structural method of depicting organic chemistry, with its use of homologous series and well-defined compound groupings (for example, amino-acids, steroids, etc.) as didactic stepping-stones. Instead, it concentrates on the reactions of the fundamental organic radical groupings in an attempt to delineate "the fundamental behavior patterns of organic compounds"; the emphasis throughout is on the practical, and theoretical concepts are kept to the bare essentials. This method of presentation combined with the succinct, factual style used throughout has produced a book reminiscent of the well-known Houben–Weyl 'Die Methoden der Organischen Chemie", of which this publication may indeed be regarded as a modern corollary. It is thus a reference work rather than a text-book and as such it performs its function admirably. It is a mine of well-arranged and well-chosen information documented by leading references characterized by their up-to-dateness; the text is remarkably free from errors, the printing clear and the binding admirable.

It should be emphasized, however, that this book is not suitable for the beginner in organic chemistry who is not completely familiar with the fundamental framework of the subject as usually taught. In my opinion the optimum usefulness of the book would accrue to graduates or near-graduates who are being initiated into research. R. A. Raphael

Industrial and Safety Problems of Nuclear Technology

Edited by Prof. Morris H. Shamos and Prof. Sidney G. Roth. Pp. xiii+368. (New York: Harper and Brothers; London: Hamish Hamilton, Ltd., 1950.) 4 dollars: 28*s*.

THIS book collects the contributions made at a three-day conference sponsored by the United States Atomic Energy Commission and Division of General Education of New York University. The subjects cover a very wide field, including a general talk by the chairman of the Atomic Energy Commission, together with an account of its contractual and patent arrangements. There are a section on radiochemistry and isotopes, one on the design and equipment of radiochemical laboratories, and finally six articles on radiation hazards, their evaluation and control.

Many of these articles are too short and scrappy to have justified publication. For example, a single article of five and a half pages on electronuclear apparatus describes particle accelerators and their protective shielding. The articles on general hazards of nuclear radiation and evaluation of radiation hazards and their control give no table of agreed tolerances.

The only articles of any substantial value are one by P. C. Aebersold on the present and potential uses of isotopes, and another by C. Rosenblum on what isotopes can mean to industry. Industry in Great Britain has been slow to realize the potentialities of isotopes as a research tool. These articles give some very interesting examples of work which has been carried out in the United States, particularly on the mechanism of synthesis of hydrocarbons and on the role of polymerization catalysts.

J. D. Cockcroft

Mothproofing

By R. W. Moncrieff. Pp. 200+10 plates. (London: Leonard Hill, Ltd., 1950.) 17*s*.

THE damage caused to wool and related fibres by certain kinds of moths and beetles has been known since the dawn of history, but it is only within comparatively recent years that a systematic study has been made of the habits of these pests and of methods for combating them. The economic importance of moth-proofing is reflected in the very large number of substances recommended for the purpose, and the appearance of a book on this subject at a time of world shortage of wool is particularly appropriate.

The first three chapters deal with the life-history of the various insects, their habits and the damage they do and, logically, should have been followed by Chapter 12 on the nutritional requirements of the larvæ. The chemistry and methods of application of the more important classes of moth-proofing substances are then described in some detail, many extracts and examples being quoted from the relevant patent specifications; the cost and fastness to washing of the various processes are also discussed. Another line of approach to the problem is one based on modification of the structure of the wool molecule, and an interesting account is given of Harris's pioneer work and of the author's glyoxal process. For the care of materials which have not been moth-proofed, special infestation precautions and remedies are called for, and the directions given in Chapter 15 will be of general interest. The concluding chapters give details of standardized procedures for breeding and rearing moths and for the larval and chemical testing of moth-proof efficiency.

The book is written in a lively and stimulating fashion and will appeal not so much to the specialist as to the general reader who wants to get a detailed picture of the progress made in this field of research. The illustrations and index are good, and there are ample references to scientific and patent literature.

British Birds

By F. W. Frohawk. Pp. 256+31 plates. (London and Melbourne: Ward, Lock and Co., Ltd., 1951.) 17*s*. 6*d*. net.

THE late F. W. Frohawk was well known not only as a sound and careful naturalist but also as no mean bird and insect artist. His accurate and beautiful sketches of British butterflies told us that. Now we have in this volume 105 colour illustrations of birds on the British list, accompanied by excellent letterpress, in which the information is given under the headings of "Distribution", "Description", and so on. It is easy to look up any species and any detail concerning it. This will be a very useful volume to the novice needing help in identification and information about habits. He will find in it all the birds normally met with in our countryside and many not ordinarily found there.

If the author and artist had lived a little longer, we may surmise the book would have been yet more comprehensive and that he would have included such species as the Scottish crested tit, which is somewhat surprisingly omitted. There are a large number of useful black-and-white sketches included in the text; there is also a helpful appendix dealing with recognition, a number of tables being given in which species are arranged alphabetically under "Haunts", "Size and Colour (General Impression)", "Head", Wings", "Flight", etc.

Reverting to the colour plates, colour reproduction is notoriously tricky, and it may be doubted if every reproduction does justice to the originals, for in some cases the tints are a little hard; however, the volume as a whole is excellent and it will form an admirable present for the young person with bird-watching aspirations, who should read the paragraph on "Record Keeping" and mark the last sentence concerning the value of accurate notes . . . "This type of record-keeping forms the only alternative to the destruction of many of our finest and rarest birds whose skins are kept for 'identification purposes' ".

Frances Pitt

ACOUSTICS OF THE ROYAL FESTIVAL HALL, LONDON

By P. H. PARKIN

Building Research Station (Department of Scientific and Industrial Research), Watford

AT a recent meeting of the Acoustics Group of the Physical Society, the late Dr. Alex. Wood remarked that when he was a young man at the beginning of the century the problems of concert hall acoustics had been solved. Sabine[1] had recently defined and measured reverberation time; all that was necessary was to adjust the reverberation time of a concert hall to a certain optimum value and then to sit back and enjoy the music. Nowadays, Dr. Wood continued, we know that we are only beginning to discern the problems of designing a concert hall with excellent acoustics.

The theory of sound waves in rooms has received considerable attention, from Lord Rayleigh[2] to the recent publications by Morse and Bolt[3], and others. The theoretical solutions of quite simple practical acoustical problems are, however, so complicated that their application is very limited, even if all the physical factors were known. For example, it has been pointed out that the solution of the steady-state sound in a rectangular room, one wall of which has on it a few patches of absorbent flush with the surface, requires a notation of more than sixty-five symbols. When we remember that musical sounds are mostly transient in character, it is clear that for some time to come the approach must be an experimental one. With so incomplete a background it may be asked[4] why science should be consulted at all in the design of a concert hall. The answer is that the man of science forms a link between the architect and the musician: however imperfect the scientific knowledge, it is a better basis than any other for the intelligent guesses which have to be made.

One major contribution of science to the design of the Royal Festival Hall on the South Bank, London, has been an attempt to assess and define the musical requirements. Hitherto the worker in acoustics has tended to rely on his own subjective judgments, an unethical practice, but one which has been largely forced on him by the lack of organized musical opinion. This assessment started in 1947 when a questionnaire was sent to all professional musicians who could be classified as listeners (as distinct from performers), in which they were asked their opinions on the acoustics of ten selected concert halls. Also, listening tests were made in several halls, where teams of listeners sat successively in different positions during concerts. From such tests as these; from public meetings such as the one organized by the Acoustics Group of the Physical Society[5,6] where musicians, architects, engineers and physicists met to discuss the problems; and from private discussions with musicians and other workers on the subject, it was possible to formulate the musical requirements. The positive virtues required are: (1) definition, (2) fullness of tone, (3) blending, and (4) balance; the negative virtues required are (5) a low level of intruding noise and (6) no echoes.

There is a further requirement which did not arise from these discussions, and that is for the acoustics to be reasonably uniform over the whole audience area. Professional musicians usually sit in the acoustically best seats, and are not always aware of the need for uniformity.

Turning now to the design problems, and taking the negative requirements first, the sound insulation was the second contribution of science to the design of the Royal Festival Hall. It was, of course, necessary to know the noise-levels on the site and the permissible noise-levels inside a concert hall. The outside levels, which were caused by the trains over Hungerford Bridge, were easily measured; the permissible inside levels were more difficult to determine. To reduce the external noise to inaudibility in the Hall would have required an excessively complicated structure. Instead, measurements of the sound-pressure levels due to nearby main-road traffic were made, during pauses in quiet passages of music, in two concert halls. Teams of listeners in these halls during concerts were not conscious of the intruding noise. As a design principle, it was decided to insulate the auditorium itself to this standard and not to rely on any additional insulation obtained from the surrounding foyers and corridors. The insulation of the proposed wall and roof was checked on the site by building a hut of the same construction. After the Hall had been under construction for some months, the railway authorities relaid the tracks on Hungerford Bridge, and the noise-level decreased by 18 decibels. The old rails had become badly corrugated; this phenomenon is not fully understood and the new rails may eventually become corrugated, although after two years use they have shown no sign of doing so. This reduction in the noise-level and the additional insulation due to the surrounding foyers have made the Hungerford Bridge trains completely inaudible in the auditorium. The actual insulation achieved has not yet been measured, as it is now necessary to construct microphones which will measure below the threshold of audibility.

Another possible source of noise in the Hall was the underground trains which run directly under the site. The vibrations due to these trains were measured on the foundations of the old brewery then existing on the site. The maximum vertical amplitude (peak-to-peak) was of the order of 0·0002 in. at 10 c./s., and although this amplitude of vibration is classified as 'not perceptible' to the human frame, it was very difficult to decide whether audible frequencies would be produced in the Hall, for example, by exciting wood panels. It was decided that the risk would have to be accepted without attempting structural precautions. In fact, there was the possibility in reserve of putting the underground rails on resilient mountings. In the event, one underground train out of four or five, presumably due to differences in the rolling stock, produces maximum noise-levels in the Hall of about 30 phons. This noise would not be distinguishable if it were not for the otherwise very quiet conditions. At the first test concert, 240 listeners were specially asked to listen for the trains; only eighteen thought that they could hear them, and then, of course, only when they coincided with pauses in the music.

The other negative requirement, no echoes, was met mainly by due regard to the shape of the Hall, but also by absorbent treatments of various kinds on the rear wall, along the junctions of the side walls and the ceiling, and on the side walls close to the orchestra where lateral echoes might have occurred.

There is another fault, not listed by the musicians, which may occur in halls. This is the occurrence of one or more particular eigentones with a decay time much longer than the general reverberation time. Such a fault occurred in the large concert studio in the Danish Broadcasting House, and in that case was cured by inserting Helmholtz resonators in the ceiling, tuned to absorb 63 and 98 c./s.[7]. The ceiling of the Royal Festival Hall was constructed with about twelve hundred 2¼-in. diameter holes for use with resonators if the need arose.

Dealing now with the design problems associated with obtaining the positive musical requirements, it must be emphasized that the following statements should be regarded as hypotheses. The two major requirements are for definition and fullness of tone. The meaning of definition is obvious; fullness of tone is not so obvious. Apparently musicians mean the same quality when they use such terms as warmth, richness, body, singing tone, sonority or resonance. (It should be remembered that 'resonance' has different meanings for the musician and the physicist; the "Oxford English Dictionary" defines it as the reinforcement or prolongation of sound by reflexion.) It is reasonable to assume that, other considerations apart and within limits, the longer the reverberation time the more chance there is of achieving this quality. If this is so, there must be some conflict between 'definition' and 'fullness of tone'.

Definition can be obtained by a clear path for the direct sound from all the instruments to all parts of the audience. The intensity of this direct sound will, at least for individual instruments if not for the whole orchestra, decrease as the square of the distance. In the Royal Festival Hall the intensity of the direct sound at the back of the Hall would be 20 decibels less than in the front row, while the reverberant sound, by definition, would be approximately of the same intensity throughout the Hall. Now for reasonable uniformity the ratio of direct sound to reverberant sound should not vary too greatly, and we know from Haas's work[8] that, for speech at least, the direct sound can be followed shortly after by reflexions of intensity greater than the direct sound without any loss of definition. That is to say, there is a time limit; reflexions which arrive at the listener within this limit can be classified with the direct sound and do not detract from the definition; reflexions arriving after this limit can be classified as reverberant sound and hinder definition. For speech this time is about 30 msec. and for music we can assume that it is of the same order. The canopy over the orchestra in the Royal Festival Hall is designed to reflect sound towards the rear of the Hall in order to maintain the intensity of the direct plus 'first-reflected' sound. To achieve fullness of tone, the Hall was designed to have as long a reverberation time as possible; the absorbing surfaces were kept to the minimum necessary to prevent echoes, and the volume of the Hall was made as large as was structurally possible.

The primary purpose of the four trial concerts which were held in the Royal Festival Hall before its opening was to test for faults, for example, echoes, since acoustics is a wave phenomenon and predictions based on geometrical analysis may not be borne out in practice. It was clear after the first trial that there were no major faults, and attention was concentrated on the problem of definition versus fullness of tone. Again, the professional musicians were consulted, but it soon became apparent that, for musicians conditioned by ten years of listening in over-reverberant halls, the acoustics of the Royal Festival Hall were too different for reliable and consistent judgments to be made. Thus, at one trial concert, ten out of fourteen musicians wanted more fullness of tone and accordingly some of the absorbent areas were removed, at the risk of echoes. In the event, due to the remainder of the upholstered seats being installed, the reverberation time was still the same at the next trial. Nevertheless, ten of the fourteen critics volunteered the information (they were not specifically asked) that the acoustics were now considerably improved; only two still wanted more fullness and nine wanted the Hall left as it was (and is).

When the Hall has been in use for six months, it is proposed to make a detailed survey of authoritative musical opinion on the acoustics. It seems to be generally agreed at the present time that the definition is outstandingly good, and, as a result, all the parts in the most complex modern orchestrations can be heard, presumably as the composers intended. Also, mezzo forte and pianissimo passages sound excellent, due in part no doubt to the good sound insulation; but there is some argument as to the effectiveness of the louder passages. A lot depends, of course, on the orchestral layout, which there is not space to discuss, and indeed on the standard of performance. Nor is there space to discuss the problems of balance and blend. From the performer's point of view, it is worth noting that Mr. Jascha Heifetz and Mr. Yehudi Menuhin have both remarked to the Press, one in Australia and the other in America, that the Royal Festival Hall has the best acoustics of any hall they have played in. Mr. Leopold Stokowski has also remarked to the present writer that he considers it the best hall he knows, although he would prefer a longer reverberation. In comparison with the seven concert halls which the 1947 survey of musical opinion, referred to above, showed to have good acoustical reputations, the reverberation time of the Royal Festival Hall (see Figs. 1 and 2) is the longest except for St. Andrew's Hall, Glasgow, which only achieves its exceptionally long time at the expense of troublesome echoes at the front part of the hall. Fig. 1 also shows the optimum reverberation time as a function of volume as recommended by Bagenal and Wood[9] and Knudsen and Harris[10]. The measured

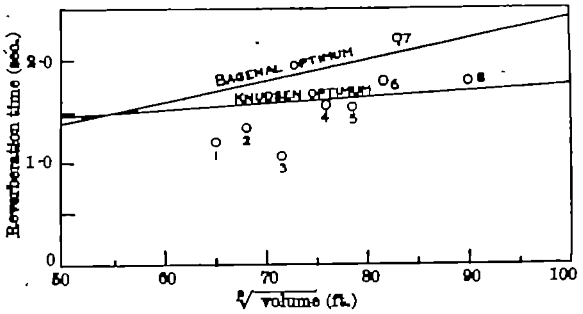

Fig 1. Reverberation times at 500 c./s. with halls full. 1, White Rock Pavilion, Hastings; 2, Peoples' Palace, London; 3, Royal Opera House, Covent Garden, London; 4, Simon de Montfort Hall, Leicester; 5, New Philharmonic Hall, Liverpool; 6, Usher Hall, Edinburgh; 7, St. Andrew's Hall, Glasgow; 8, Royal Festival Hall, London

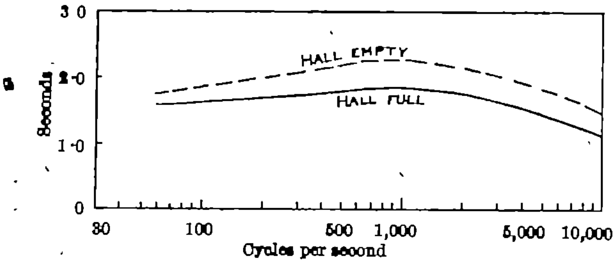

Fig. 2. Reverberation time of the Royal Festival Hall, full and empty

reverberation time takes no account of the behaviour of the sound during the first 50 or 100 msec., and it may be that because of the strong direct and first-reflected sound in the Royal Festival Hall the reverberation time could well be longer.

A final assessment must await further experience, and the problem has been elegantly put by the music critic of *The Times*, writing about one of the trial concerts[11]; after remarking that a little more 'warmth' was desirable, he continues: "Yet to be able to hear all parts within a tutti, to have the piano . . . sound in the huge hall with the intimacy of the drawing room, and really to be aware of all that is going on in a complex score like Debussy's 'La Mer' are experiences that can only be had elsewhere in the Liverpool Hall and must not be sacrificed too far to the desire of the ear for a feather bed on which to recline voluptuously".

It would not be fitting to conclude without a tribute to Mr. Hope Bagenal, the acoustic consultant, whose judgment in these problems, where so much is qualitative, has been infallible.

This work will be described in detail elsewhere; it forms part of the programme of the Building Research Board of the Department of Scientific and Industrial Research, and this article is published by permission of the Director of Building Research.

RELATIONSHIP BETWEEN HÆMOGLOBIN AND ERYTHROCRUORIN

By Prof. D. KEILIN, F.R.S., and Dr. E. F. HARTREE

Molteno Institute, University of Cambridge

THE name 'hæmoglobin' was introduced by Hoppe-Seyler in 1864[1] for the red pigment of blood which was previously referred to as hæmatoglobulin by Berzelius (1840)[2] and hæmatocrystallin by Lehmann (1853)[3]. Stokes (1864)[4], not being aware of these terms, proposed for this pigment the name 'cruorine'. In 1868 Ray Lankester[5] announced the discovery of 'Stokes's Red Cruorine' in non-corpuscular vascular fluids of *Lumbricus*, *Eunice sanguinea* and *Hirudo*, in blood plasma of *Planorbis corneus* and in the body fluid of the larva of *Chironomus plumosus*. He noted that "in vertebrates the Red Cruorine is concentrated in corpuscles, whilst in the Mollusc, Insect and Annelid, it is diffused in the plasma". In some annelids, including *Sabella*, he found that vascular fluid contains "a green body of the same nature as the Red Cruorine of Stokes". He concluded that this "green body may be called Chloro-cruorine whilst the red is termed Erythro-cruorine. There is an indication of the existence of a violet and yellow form of cruorine in certain Molluscs. Many Annelids, very nearly all Insects, Crustacea and Molluscs have not a coloured Cruorine in their blood. Is it not probable that they possess a colourless body possessing the same oxygen-carrying properties which Stokes attributes to Red Cruorine? If so it should be classed with the red and green forms as a modification of Cruorine."

There is no doubt that Ray Lankester used the term erythro-cruorine to cover all red oxygen-carrying pigments both of vertebrates and invertebrates. However, in 1870, while retaining the term chloro-cruorine for the green pigment, Ray Lankester[6] abandoned the term 'erythro-cruorine', replacing it both in the case of vertebrate and invertebrate pigments by Hoppe-Seyler's term 'hæmoglobin', which was by this time generally accepted.

More recently, Ray Lankester's term erythrocruorin (with slightly different spelling) was revived by Svedberg and Eriksson[7] to designate the red blood pigments of *Arenicola marina* and *Lumbricus terrestris*. The reason they gave for so doing was formulated as follows: "The detailed ultracentrifugal investigation has shown that the red respiratory pigment dissolved in the blood of these worms is with regard to the properties of the protein part of the molecule, more allied to chlorocruorin and to hemocyanin than to hemoglobin of the vertebrates. It therefore seems inappropriate to call it a modification of hemoglobin"; and further, "It seems to us appropriate to revive Ray Lankester's term and we therefore propose the name erythrocruorin for the red respiratory proteins of the invertebrates". With the limited information then available, the contrast between erythrocruorin and hæmoglobin was well defined: erythrocruorin being dissolved in plasma, having a high molecular weight (*c.* 3,000,000) and a low isoelectric point (~ 4·8); hæmoglobin being intracorpuscular, having a lower molecular weight (*c.* 68,000) and a higher isoelectric point (6·5–7·5).

The term 'erythrocruorin' was extended by Svedberg and Eriksson-Quensel[8], Svedberg and Pedersen[9], Roche[10] and Roche and Fontaine[11] to the hæmoglobin-like pigments of all invertebrates as well as of cyclostome fishes among the vertebrates, the name 'hæmoglobin' being reserved for the blood pigments of all other vertebrates.

This classification was based by them upon determinations of (1) the molecular weight, (2) the isoelectric point, and (3) the chemical composition of the proteins of these pigments. However, as will be shown presently, a thorough analysis of the results obtained under the above headings does not support the separation of these pigments into hæmoglobins and erythrocruorins.

(1) *Molecular weight.* Determinations of molecular weight of different oxygen carriers have been summarized and tabulated by Svedberg and Pedersen[9].

Table 1. Molecular Weights of Different Hæmoglobins (II) and Erythrocruorins (I and III) according to Svedberg and Pedersen (ref. 9)

Lampetra	17,000	I
Chironomus	17,000 34,000	
Glycera	34,000	
Fishes, birds and mammals	68,000	II
Amphibia and reptiles	68,000 150,000 290,000	
Daphnia	400,000	III
Planorbis	1,630,000	
Arenicola	3,000,000	
Lumbricus	3,000,000	

Thus, the molecular weights of erythrocruorins found dissolved in the plasma of different invertebrates vary from 17,000 to about 3,000,000 (I and III, Table 1). The values for intracellular erythrocruorin both of certain invertebrates and of cyclostomes are 17,000 and 34,000 (I, Table 1). The pigment in *Daphnia* contains a main component of molecular weight about 400,000 ($S_{20} = 16\cdot3 \times 10^{-13}$) and varying proportions of a smaller molecular species (about 44,000) which at *p*H 8 may constitute as much as 40 per cent of the total pigment. The hæmoglobins of mammals, birds and fishes have the mean value $S_{20} = 4\cdot3 \times 10^{-13}$, which corresponds to a molecular weight of 68,000, while those of amphibians and reptiles have a somewhat higher value: $S_{20} = 4\cdot7 \times 10^{-13}$. What is, however, of special interest is that the blood of these vertebrates, according to Svedberg and Pedersen[9], "nearly always contained a second component having S_{20} about 7×10^{-13} and probably having twice the molecular weight of normal hæmoglobin. Furthermore, in a single case a third component was observed with $S_{20} = 12\cdot5 \times 10^{-13}$ (molecular weight probably 4 × hæmoglobin)." In other words, the intracorpuscular hæmoglobin of certain amphibians (for example, *Bufo valliceps*) may reach values as high as 150,000 and 290,000. The molecular weights of the intracorpuscular hæmoglobins of vertebrates (68,000–290,000) occupy a comparatively small range (II, Table 1) within the very wide limits of molecular weights exhibited by erythrocruorins, which may vary between 17,000 and 3,000,000 (I and III, Table 1). Molecular weight data, therefore, give no support to the separation of these pigments into two groups.

Table 2. Isoelectric Points of Different Respiratory Pigments (see Svedberg and Pedersen (ref. 9), and Roche and Fontaine (ref. 11)). I.P. of *Gastrophilus* according to Keilin and Wang (ref. 15)

The line drawn between *Gastrophilus* and toadfish separates the so-called 'erythrocruorins' from hæmoglobins

	Isoelectric points
Arenicola	4·6
Chironomus	5·4
Lampetra	5·7
Notomastus	6·0
Gastrophilus	6·2
Toadfish	5·75–6·23
Cyprinus	6·5
Horse	6·9
Man	7·1
Duck	7·5

(2) *Isoelectric points.* The isoelectric points (I.P.) of respiratory pigments, as shown in Table 2, vary from *p*H 4·6 to *p*H 7·5. Although precise determinations have so far been carried out in only a few cases[9,11,15], yet within the above range no distinct break in the values can be observed. The line drawn between *Gastrophilus* and toadfish separating the pigments into erythrocruorins (I.P. 4·6–6·2) and hæmoglobins (I.P. 5·75–7·5) is a purely arbitrary division.

Table 3. Amino-Acids in Respiratory Pigments according to Roche (ref. 10) and Roche and Fontaine (ref. 11)

Respiratory pigment of	Pigment classified as	Arginine (per cent)	Histidine (per cent)	Lysine (per cent)	Cystine* (per cent)
Lampetra	Erythrocruorin	3·52	3·37	7·51	4·40
Arenicola	,,	10·04	4·03	1·85	4·08
Glycera	,,	9·64	5·39	4 90	3 40
Lumbricus	,,	10·07	4·68	1·73	1·47
Sabella (= *Spirographis*)	Chlorocruorin	9·64	2·38	3·64	1·64
Horse	Hæmoglobin	3·57	8·13	8·31	0·74
Horse (according to Tristram, ref. 28)	Hæmoglobin	3·65	8·71	8 51	1·01

* Cystine: the value of 1·01 given by Tristram is the sum of cysteine and cystine. Roche's figures were obtained by a method which also gives the sum of these acids.

(3) *Amino-acid content of proteins.* The estimation of a few amino-acids in pigments classified as erythrocruorins was carried out by Roche and Fontaine[11] in four cases (*Lampetra*, *Arenicola*, *Glycera* and *Lumbricus*) and a comparison was made with amino-acids in chlorocruorin of *Sabella* and in horse hæmoglobin. However, since some of this material was available only in small amounts and was of doubtful purity, the estimations can be considered as only approximate. Even if we accept the values shown in Table 3, there is no indication of uniformity in amino-acid distribution among different erythrocruorins. Whereas the arginine and lysine contents of *Lampetra* erythrocruorin are very similar to those of horse hæmoglobin, the values for histidine and cystine are not far from those found in the pigments of the invertebrates. On the other hand, if their cystine contents are compared, the pigment in *Lumbricus* is more closely allied to horse hæmoglobin than to the pigment in *Arenicola*. Thus, the amino-acid contents of these oxygen carriers do not support their separation into erythrocruorins and hæmoglobins.

Other Properties of Oxygen Carriers

The comparative study of protohæm–protein oxygen carriers of different origin reveals that they differ between themselves not only in the three properties examined above, namely, their (1) molecular weight, (2) isoelectric point, and (3) amino-acid content, but also in other important properties, such as: (4) solubility, (5) ease of crystallization, (6) crystalline structure, (7) affinity for oxygen, (8) relative affinity for oxygen and carbon monoxide, (9) shape of the oxygen dissociation curve, (10) absorption spectrum, (11) autoxidizability of the iron, (12) ease of denaturation by alkali and other factors, and (13) antigenic properties.

Unfortunately, only three of these properties have been investigated more or less systematically for respiratory carriers both of vertebrates and invertebrates. These are: affinities of the pigments for oxygen, their relative affinities for oxygen and carbon monoxide and the positions of their absorption bands in the visible region of the spectrum.

Affinity of the respiratory pigments for oxygen. This can be expressed in terms of the oxygen tensions in millimetres of mercury (p_{50}) at which the pigments are half-oxygenated. This property has been extensively investigated because of its great physiological significance. The scattered literature on this subject up to 1933 was collected and critically reviewed by

Table 4. Affinities of Respiratory Pigments for Oxygen
Oxygen tensions (p_{50}) in mm. mercury, for 50 per cent oxygenation of pigments in the blood of different organisms; (*a*) as determined by Fox (ref. 13), (*b*) as quoted by Redfield (ref. 12). The pigments of organisms named in italics are classified by Svedberg and Roche as erythrocruorins

		p_{50}		
		17° C.; no carbon dioxide	17° C.; + 1 per cent carbon dioxide	38° C.; + 5 per cent carbon dioxide
(*a*)	*Chironomus riparius*	0·6	0·6	
	Tubifex sp.	0·6	—	
	Ceriodaphnia laticaudata	0 8	1·0	
	Thalassema neptuni	1·4	1·8	
	Arenicola marina	1·8	2·6	
	Planorbis corneus	1·9	2·9	
	Daphnia magna	3·1	4·9	
	Man	1·2	3·9	
(*b*)	Man			26
	Horse			26
	Sea lion			40
	Eel	2–3		
	Pike	2–3		

Redfield[12], while more recently Fox[13] has determined p_{50} for a number of invertebrate pigments by microspectroscopic methods. A few examples selected from these papers as having a direct bearing on the relationship between oxygen carriers of vertebrates and invertebrates are given in Table 4. In all cases the determinations were carried out on whole blood. To these examples we can add the values of p_{50} = 0·1 mm. at 15° obtained by Keilin and Wang[14] for the hæmoglobin of the root nodules of leguminous plants and p_{50} = 5 mm. at 39° obtained by Keilin and Wang[15] for the hæmoglobin of tracheal cells of *Gastrophilus* larvæ. An exceptionally high affinity for oxygen is shown by the hæmoglobins of *Ascaris lumbricoides*. This organism, as was found by Keilin[16], has two distinct hæmoglobins, one in the perienteric fluid, the other in the body wall. It was recently shown by Davenport[17] that both these hæmoglobins exhibit a remarkable resistance to deoxygenation. Thus, in the presence of sodium hyposulphite the half-time (t_{50}) for deoxygenation is 150 sec. for perienteric and 80 sec. for body-wall hæmoglobins, as compared with 0·008 sec. for sheep hæmoglobin.

All the available data clearly indicate that p_{50} values, like the oxygen dissociation curves, do not follow at all the classification of pigments into hæmoglobins and erythrocruorins. On the contrary, they only reflect more or less consistently the physiological requirements of the organisms, such as can also be illustrated by the relationship between blood hæmoglobin and myoglobin of the same organism, or between maternal and fœtal hæmoglobins. Moreover, since p_{50} decreases when a solution of hæmoglobin is diluted[18], a comparison of the pigments in Table 4 at equal hæmoglobin concentrations would, if anything, further diminish the distinction between hæmoglobins and erythrocruorins.

Relative affinity of the respiratory pigments for oxygen and carbon monoxide. This ratio is expressed as an equilibrium or partition constant

$$K = \frac{[\mathrm{HbCO}]pO_2}{[\mathrm{HbO_2}]pCO}.$$

The value of this constant for the hæmoglobins of certain vertebrates was determined by Anson, Barcroft, Mirsky and Oinuma[19]. The problem was recently carefully re-investigated by Fox[20], who determined this constant for the oxygen carriers of several vertebrates and invertebrates. The results of these determinations, together with the data obtained for the pigments in the root nodules of leguminous plants[14] and the tracheal cells of *Gastrophilus* larvæ[15] as well as for myoglobins of different mammals, are summarized in Table 5.

Table 5. Values of $K = \frac{[\mathrm{HbCO}]\,pO_2}{[\mathrm{HbO_2}]\,pCO}$ for different respiratory pigments according to Fox (ref. 20), except for root nodules and *Gastrophilus* (Keilin and Wang, ref. 14, 15). Pigment of *Branchioma* is chlorocruorin; those marked with an asterisk belong to the supposed erythrocruorins, the remainder to the hæmoglobins

	K
Branchioma	570
*Chironomus**	400
Horse	280
Man	230
*Arenicola**	150
*Tubifex**	40
*Planorbis**	40
Rabbit	40
Root nodules*	37
*Gastrophilus**	0·67
Myoglobins	28–51

As in the case of oxygen affinities, no line can be drawn separating the values of K for erythrocruorins and hæmoglobins.

Absorption spectra. That the absorption spectra of hæmoglobins of different origins are not the same was shown for the first time by Sorby[21] in 1876 in his classical paper "On the Evolution of Hæmoglobin". In comparing human and *Planorbis* hæmoglobin, he found that the absorption bands of the latter lie about 3 mμ nearer the blue end of the spectrum. Sorby did not fail to give the correct interpretation of this phenomenon, as the following quotation shows: "This difference cannot be due to any difference in the physical state of the substance since in both cases it was perfectly dissolved in a relatively large quantity of water. It is rather of such a character as would result from the substitution of one kind of albuminoid for another in the combination with the same modification of hæmatin, into which both are decomposed when boiled with ammonia or decomposed by acids." Sorby also found that these pigments differ in their susceptibility to heat and to acids. These observations were confirmed by Vlès[22] and by Anson *et al.*[19], who extended them to hæmoglobins of a greater variety of organisms. However, since most of these data were obtained with impure material and not with modern and more precise spectrophotometric methods, they can only be considered as approximate and need not be recorded here. Nevertheless, they clearly show that the positions of the absorption bands of different hæmoglobins are irregularly distributed between those of pigments classified as erythrocruorins.

General Considerations

Although the oxygen carriers of different organisms show marked differences in their properties, not one of these properties supports the classification of the hæm–protein compounds into erythrocruorins and hæmoglobins. In fact, it is primarily the important advance made in the study of this subject by Svedberg himself that has made it impossible to retain the term 'erythrocruorin' which he introduced during the first stage of his work on the oxygen carriers of invertebrates. The term 'erythrocruorin' can therefore be abandoned and all protohæm–protein oxygen carriers should now be brought together under the general term 'hæmoglobin'. The specific cases of these pigments can be referred to as hæmoglobins with an appropriate indication of their origin; for example, human hæmoglobin, *Planorbis* hæmoglobin, *Gastrophilus* hæmoglobin, etc. Muscle hæmoglobin can be referred to as myohæmoglobin, which is usually abbreviated to myoglobin.

The hæmoglobin of the root nodules of leguminous plants is of special interest. It was discovered by Kubo[23] and its oxygenation was demonstrated by Keilin and Wang[14], who also determined the spectrophotometric curves of its main derivatives and its affinities both for oxygen and carbon monoxide. What is remarkable, however, is that neither the plant cells alone nor the symbiotic micro-organism (*Rhizobium*) cultivated separately are capable of synthesizing hæmoglobin. It is only when the root cells are invaded by the specific micro-organism and begin to proliferate that hæmoglobin is formed. *Rhizobium* not only induces growth and multiplication of the cells but also supplies these proliferating cells directly or indirectly with a factor necessary for synthesis of hæmoglobin[14]. Root nodule, or simply nodule, hæmoglobin is an appropriate name for this pigment, since it gives sufficient indication of its peculiar localization and dependence upon an association between the plant cells and *Rhizobium*. (The name 'leghæmoglobin' proposed for this pigment by Virtanen[24] is not suitable since the prefix 'leg' is not an adequate abbreviation of the Latin *legumen* and is ambiguous in English.)

We shall now briefly consider the term 'chlorocruorin' which was introduced by Ray Lankester in 1868 for the green blood pigment of certain polychæte worms. Chlorocruorin was re-investigated by Fox[20,25,26], who, in a series of important papers on this pigment, established its characteristic properties. Chlorocruorin differs from hæmoglobin in the structure of its hæm as well as that of its protein. The hæm, according to Fischer and Seemann[27], differs from protohæm in having one of its vinyl side-chains replaced by a formyl group. The term 'chlorocruorin' should be retained, since it indicates the green colour of the pigment; it also suggests a marked difference from hæmoglobin and is closely associated with the extensive investigations on this subject by Fox and other workers.

It may be interesting to mention here that the blood of polychæte worms generally contains either hæmoglobin or chlorocruorin or is devoid of both pigments. However, it was recently found by Fox[20] that the genus *Serpula* differs from all other known organisms in possessing two oxygen carriers, hæmoglobin and chlorocruorin, in the blood plasma.

Since the prosthetic group of all hæmoglobins is the same protohæm nucleus, the differences in their properties, as was clearly formulated by Sorby[21], is due to differences in the nature of the protein portions of their molecules. What is of special importance is that in spite of the great variety in the amino-acid contents of these proteins and the great diversity in their physico-chemical properties, they all have one character in common, and that is the ability to impart to the hæm nucleus the remarkable property of reversible oxygenation. This important property, which cannot be imitated by any other naturally occurring or synthetic compound, depends upon the integrity of the structural configuration of the protein and is abolished when the protein undergoes denaturation. By bringing together all protohæm-protein oxygen carriers into the one group—hæmoglobin—one's attention becomes rightly focused upon their common fundamental property of reversible oxygenation, the intimate mechanism of which still awaits elucidation.

To avoid confusion and unnecessary complications of nomenclature, the classification of all biologically active protein compounds, such as oxygen carriers or enzymes, should be based not upon their physico-chemical properties as proteins but upon their specific biological activities and the nature of their active, or prosthetic, groups.

THE COSMIC RAY OBSERVATORY AT OTTAWA

By Dr. D. C. ROSE

National Research Council of Canada

THE National Research Council of Canada has recently constructed at Ottawa a small observatory for cosmic ray measurements. Such an observatory at or near sea-level (the present site is about 200 ft. above mean sea-level) may be considered novel at a time when so much important work is being done at high altitude. There are still, however, many interesting things to be learned from sea-level measurements, and the advantages of fixed rather than airborne apparatus are great. Practically all the nuclear phenomena (probably all except collisions due to heavy energetic primary particles) occur at sea-level, though less frequently than at higher altitude. Many experiments which require continuous observation can only be carried out with fixed equipment, and few long-term measurements which depend on geomagnetic effects have been taken at the high geomagnetic latitude (56·8° N.) at which the new laboratory is situated.

The programme of work, which was started about three years ago and was moved recently to the new observatory, includes the study of the nature of cosmic ray particles and showers at sea-level, and experiments which would lead to more information about the source of cosmic rays.

The new building was designed to supply laboratory facilities wherein the amount of absorbing material

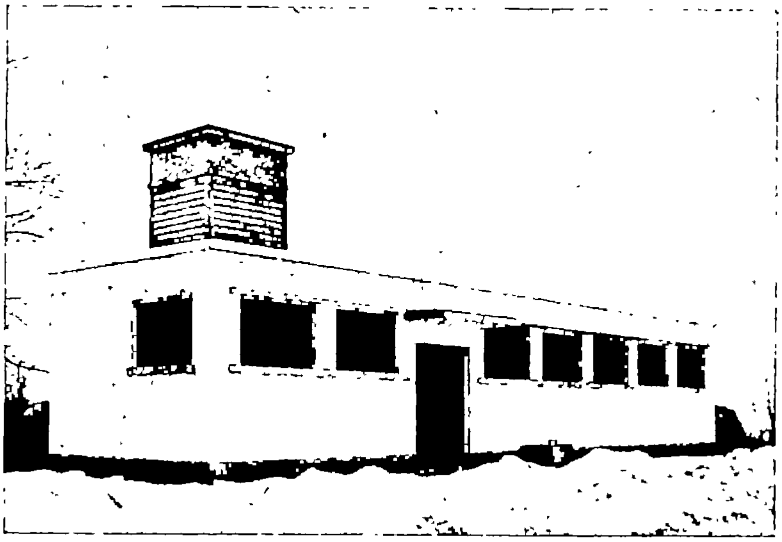

Fig. 1. The cosmic ray observatory at Ottawa (December 1950)

could be known and varied at will without interfering with building structures. Further, the increasing use of accelerators and radioactive material was putting serious limitations on the cosmic ray measurements that could be taken at the main laboratory headquarters of the National Research Council. A site was chosen well away from other buildings and located on high ground with a clear vista in all directions from the roof.

The building is essentially an observatory and has no space for the construction of apparatus. These facilities remain in the main laboratory, about four miles away. The observatory is, however, located in the same area as the aeronautical and mechanical engineering laboratories of the National Research Council, so supplies are readily available. There is also transportation every hour throughout the day each way from this area to the main laboratories.

The inside dimensions of the building are 50 ft. by 12 ft., and except for a small wash-room and dark-room at one end, the interior is not partitioned. It is one story high and has a flat roof, the roof being used for experimental purposes. An area on the roof, 6 ft. by 12 ft. at one end, is reinforced to carry heavy loads up to 10 tons. The rest of the roof is designed for 50 lb. per square foot, so that it can carry lighter equipment.

There is an opening in the roof six feet square over the centre of the laboratory space. This opening has a movable cover which in suitable weather may be left off, or at other times covered with light weather-proof material of known absorbing power. Experiments in which the exact quantity of absorber overhead must be known can, therefore, be carried out anywhere on the roof if the total weight is low, on the reinforced area if the weight is large, or in the laboratory below the opening. For work on the roof, which is carried out in all weathers, movable penthouses have been constructed. These are heated electrically and the temperature is controlled.

The floor of the laboratory is of hard wood laid on concrete. The concrete was poured on a rock fill about two feet thick lying on solid rock. The floor will, therefore, hold very heavy loads, and there is no hesitation in building a lead castle weighing several tons around measuring apparatus in any part of the laboratory.

The building and the furniture, with the exception of a desk and chairs, are of fire-proof construction, the floor and the window frames being the only wood in the structure. This fire-proof construction was followed because a considerable quantity of electronic and recording apparatus is left running continuously, and even with careful engineering it is possible that something may become overheated and start a fire. The building is left unattended for long periods, at night and over week-ends, and an attempt has been made to arrange all equipment which is operating continuously so that, should one component burn up when there is no one in attendance, it will do no more harm than put that piece of equipment out of order and make a certain amount of smoke. Fig. 1 shows a picture of the building from the front, and Fig. 2 is an inside view showing a rack of scalers and recording apparatus.

The plans for the equipment of the observatory included ionization chambers, Geiger–Muller counters with associated coincidence and anti-coincidence circuits, proportional counters and Wilson cloud chambers. Up to the present, there has been some specialization in Geiger–Muller counter work and ionization chambers. Wilson cloud chambers have not yet been used, but will be built in the near future. The facilities for the construction of apparatus in the National Research Laboratories are considerable, and all the apparatus except the Geiger–Müller

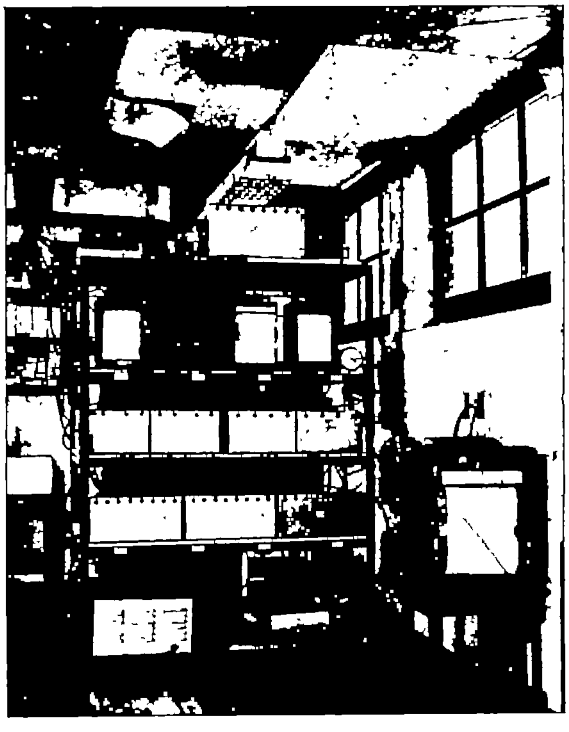

Fig. 2. Rack carrying scalers and recording equipment. The recorder at the right is a differential rate meter

tubes themselves and the recording instruments are constructed in the laboratories.

One of the important experiments is to keep a continuous watch for sudden increases in the cosmic ray intensity associated with solar flares, such as that observed on November 19, 1949[1]. Counter telescopes are used for these measurements. Another major investigation being undertaken with counter telescopes is a thorough study of north–south and east–west asymmetry in cosmic ray intensities. At high geomagnetic latitudes and particularly at large zenith angles, the north–south asymmetry is as prominent as the east–west differences, and both may be sensitive to geomagnetic disturbances.

Counters are also being used in a study just completed of the directional intensity of mesons and in another on the angular spread of penetrating showers. This latter experiment is being followed up by a study of the production of local penetrating showers in different materials. For this study, large quantities of absorbing materials of different atomic weight, namely, lead, copper, aluminium and carbon, have been obtained.

An attempt has been made to standardize some of the electronic equipment used in the observatory. Versatile equipment has been developed in such a way that any arrangement of counter trays in coincidence and anti-coincidence up to sixfold can be made just by plugging the components together and making simple adjustments of one set of bias voltages. Each counter tray has a simple preamplifier which also partially quenches the counter. (Self-quenching counter tubes are used, but the quenching circuit is believed to prolong the life of the counters.) This is followed by a cathode follower stage with a low impedance output, so that the signal may be carried twenty feet or more by cable. It then goes through a pulse-shaping and discriminating circuit ending in a pulse about three microseconds long. This pulse is then fed into mixing stages (up to three-fold) by adding the signals at the grid of the mixing pentode rather than by the more conventional Rossi circuit. For higher orders of coincidence, the output of a mixing stage may be fed to further mixing stages or a Rossi circuit.

From here it is fed to scaler circuits. The scaler circuits are all of the binary type, built in units of two stages, four stages, and eight stages. The output of the scalers will operate telephone message registers or one circuit of an Esterline Angus twenty-pen operations recorder or both in parallel. All the circuits have been designed for continuous operation, and quite complicated arrangements have often been operated for months without adjustment.

The observatory is now equipped with about forty scalers, and about thirty double- and triple-coincidence units, mixing units, units for higher order coincidence or anti-coincidence arrangements. Counter trays with their preamplifiers are usually made to fit experimental arrangements as required.

Besides the investigations mentioned above, an investigation is in hand on the range spectrum of mesons at this observatory both by coincidence and anti-coincidence arrangements of counters. Delayed coincidence in which the meson is detected by its decay electron is also used.

Proportional counters were used in an experiment designed to look for highly ionizing particles in cosmic rays at sea-level. The results were negative; but they produced an interesting study of the statistical variations in the production of ions along the path of an ionizing particle. Two large high-pressure ionization chambers have been constructed which are being used for continuous intensity measurements and a study of bursts. Both photographic recording with an electrometer and a vibrating reed electrometer are being used with these.

Associated with this observatory is a cosmic ray station in the Canadian Arctic (geomagnetic latitude 83·0° N.) at one of the joint Canadian–American weather stations. Continuous measurements have been taken for about two years, and during the 1950–51 winter, a programme of work there was undertaken in which an accurate comparison of intensities and the spectral distribution of mesons were made. At present a watch is being kept there for the sudden increases in intensity associated with solar flares.

The staff of the group normally consists of three physicists on the National Research Council staff and three technicians. There is room for three post-doctorate Fellows; these fellowships are offered by the National Research Council of Canada to students of Ph.D. standing who wish to work in Canada for a period before taking a permanent post.

DETERMINATION OF THE ABSOLUTE CONFIGURATION OF OPTICALLY ACTIVE COMPOUNDS BY MEANS OF X-RAYS

By PROF. J. M. BIJVOET, A. F. PEERDEMAN
AND
A. J. van BOMMEL
van 't Hoff Laboratory, University of Utrecht

J. H. VAN 'T HOFF extended the structural formulæ of organic chemistry to include spatial configuration ("La chimie dans l'espace" (1874), the aliphatic carbon atom with hydrogen or other atoms at the corners of a tetrahedron surrounding it). X-ray analysis has determined the exact configurations and the interatomic distances accurately to within a hundredth of an angstrom unit.

Optically active compounds are not superimposable and are the inverted image of each other. Now it is a remarkable fact that while all details of such configurations can be determined, it yet remained unsolved, whether model or inversion corresponds with a given—say the dextrorotatory—compound. Our present investigation was concerned with this question.

It is impossible to determine absolute configurations by chemical means, which show only the relationship between different structures. These relationships would not alter in any respect if every optically active compound should possess its inverted configuration. Absolute configurations—introduced for the sake of expressing relationship—were based on mere convention. Emil Fischer attributed the configuration of Fig. 2*b* to natural, dextrorotatory, tartaric acid—with an even chance that this choice would fit the real situation.

Of the physical methods of determining absolute configuration, the theoretical calculation of the rotatory power is the most obvious and that most studied; hitherto, the results, however, have lacked conclusiveness. Recently, a discussion of the relation between crystal structure and face development has been put forward. As to the X-ray method, X-rays are not supposed to be able to determine absolute configuration as they measure the interatomic distances, which do not differ for model and inversion.

This condition may be illustrated by the simple schematic diffraction experiments indicated in Fig. 1. Compared with (*a*), the diffraction object in (*b*) has been inverted. The path (phase) differences for each pair of atoms involved in the same direction of diffraction (*p*) remains unchanged (except for sign); hence the resultant interference effect will be the same for both conditions. The removal of this equivalence is the essential point of the determination of absolute configuration by X-rays.

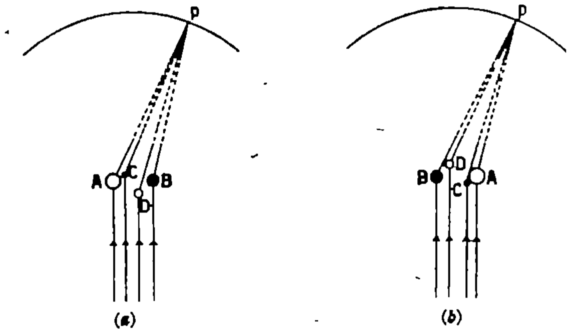

Fig. 1. Equal phase differences (except for sign) for model and inversion in the same direction of diffraction. By introducing a phase-lag in the scattering of one of the atoms, this equivalence is removed

A phase-lag can be introduced into the primary scattering process by one of the atoms[1], say atom *A*. This is achieved by using X-rays of a wave-length that just excites atom *A*. Again, for the conditions (*a*) and (*b*), compare the phase differences operative in the diffraction *p*. Consider the phase difference between the waves scattered by the atoms *A* and *B*. In (*a*) the characteristic phase-lag in the scattering of atom *A* is seen to be connected with the longer light path, in case (*b*) with the shorter. Hence, the total phase difference operative in the interference of the waves scattered by *A* and *B* will no longer be opposite, and the diffraction intensities will differ for these two conditions. (In the crystal diffraction, besides the inequality $I^a_{hkl} \neq I^b_{hkl}$ (*a* and *b* denoting the two optical antipodes) the following relation exists: $I^a_{hkl} = I^b_{\bar{h}\bar{k}\bar{l}}$. According to the latter relation, the films of optical antipodes do not differ in diffraction intensities, but only in their succession on Weissenberg diagrams with fixed rotation sense of the crystal.)

This difference of corresponding diffractions, which vanishes for X-rays of arbitrary wave-length, has been observed in the case of sodium rubidium tartrate using zirconium $K\alpha$ rays which just excite the rubidium atom[2]. It enabled us, analogous to the case discussed above, to decide between the diffracting model and its inversion. The result is that Emil Fischer's *convention*, which assigned the configuration of Fig. 2 to the dextrorotatory acid, *appears to answer to reality*.

Obviously, the agreement between conventional and real model then also embraces all compounds, the configurations of which—relative to tartaric acid—have been determined. Details are given in ref. 2 and in a forthcoming paper in *Acta Crystallographica*. (A preliminary account was given by one of the authors (J. M. B.) at a conference in Pennsylvania State College in April 1950.)

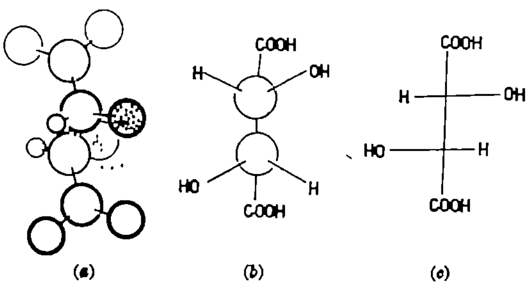

Fig. 2. Absolute configuration of natural dextrorotatory tartaric acid

a, As determined by X-rays in sodium rubidium tartrate.
b, In normalized configuration by rotating around single bonds.
c, In projection.

The question of nomenclature is beyond the scope of our investigation. Absolute configuration determined, the standard substance for which hitherto a configuration had to be assumed becomes a redundant concept. The problem of nomenclature now concerns given configurations, and requires a notation which denotes these configurations in an unambiguous and if possible self-explanatory way. The usual notations like D_g or L_s for dextrorotatory tartaric acid, based on chemical relations, seems rather unsatisfactory from the latter point of view. For a recent study of the problem reference should be made to the literature[3].

We wish to thank the Netherlands Organization for Pure Research (Z.W.O.) for its support of this investigation.

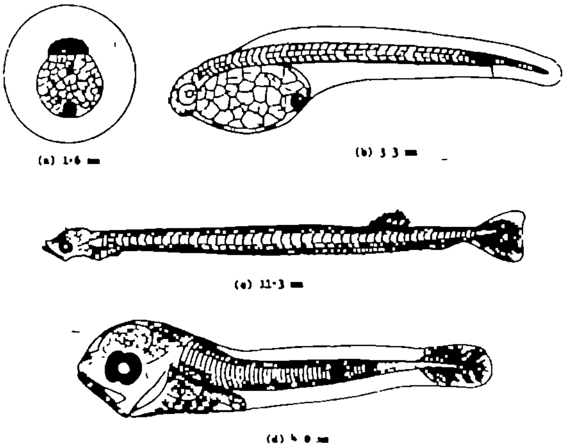
BREEDING GROUND OF PILCHARDS OFF THE COAST OF SOUTH-WEST AFRICA

By Dr. T. J. HART
National Institute of Oceanography
AND
N. B. MARSHALL
British Museum (Natural History)

During the recent whale-marking voyage of the R.R.S. *William Scoresby* (Lieut.-Commander A. F. Macfie), notable concentrations were found of the eggs and larvæ of the pilchard (*Sardinops sagax*) off the coast of South-West Africa. In view of the large scale of the modern South African pilchard fishery, this indication of the breeding ground, hitherto unknown, is likely to be of considerable importance.

The R.R.S. *William Scoresby* is equipped for making oceanographical surveys, and it had been arranged that during her passages between whaling grounds in the Atlantic and Indian Oceans the



Early stages in the life-history of the pilchard, *Sardinops sagax* (Jenyns), and the stockfish, *Merluccius capensis* Castelnau, from South-West African waters · (*a*) developing egg, 1·6 mm. ; (*b*) a newly hatched larva, 3·3 mm. ; and (*c*) a post-larva of the pilchard, 11·3 mm.; (*d*) post-larva of the stockfish, 4·0 mm.

opportunity should be taken to make detailed studies of the plankton and water conditions in the Benguela Current. The main purpose was to obtain a closer understanding of the exceptional organic productivity of the region, and to compare its main features with those of the still more productive region in the Peru Current, for the investigation of which the same vessel was used in 1931 under the Discovery Committee. The work off the African coast was mainly between 19° and 29° S., and two surveys were made, in March and September 1950.

During the sorting of the material collected during the first survey, large catches of clupeoid eggs, larvæ and post-larvæ, have been noted, and they have been identified as belonging to *Sardinops sagax* (Jenyns) (see diagram). The preliminary examination gives a clear indication that spawning took place within twenty-five sea-miles of the coast in depths of 50–150 metres throughout the area surveyed, but mainly between 22° and 26° S. A few post-larvæ were taken in deeper net-hauls, but none in the deeper, warmer water outside the continental shelf. The eggs were found where the mean temperatures of the upper 50 m. of water were less than 17·5° C., the heaviest catches being made where the mean temperature was between 13° and 14·5° C. This suggests a close parallel between the spawning temperature of this species and the limits established for the California pilchard (*S. cœruleus*), for which the inclusive temperature range was found to be 12·5°–16·5° C. The season (early autumn) in which the South African pilchard was found to be spawning is not remarkable, since closely related clupeoid fishes in Australian and European waters spawn at opposite seasons near the extremes of their geographical distributions. Information about the spawning in other seasons off the African coast is limited to the R.R.S. *William Scoresby's* second survey (spring), and the preliminary examination of the catches indicates that very little spawning had taken place and only at two stations close inshore.

A quantitative comparison between the abundance of eggs and larval stages taken off the African coast with observations on related species in other regions is rather uncertain, because of the difference and variability of the filtering power of the nets and sampling procedures that have been used; but a conservative estimate suggests that the richest hauls off the African coast in early autumn represent spawning concentrations considerably greater than those reported in European and Californian waters. It seems probable, therefore, that the spawning of *S. sagax* may have been near its climax in early autumn.

During the sorting of the plankton collections, some association was noted between the occurrence of the pilchard eggs and the increasing abundance of *Fragilaria* ribbons among the diatoms; also with the occurrence of *Cladocera* among the smaller crustaceans and of polychæte and lamellibranch post-larvæ. But these features are part of the increasingly neritic facies of the community as land is approached, and are apparent at other seasons. The catches of Cumacea (mainly *Iphinoe* sp.) corresponded very closely with the pilchard egg numbers, and these particularly, being comparatively large and easily recognized, might prove to be useful pointers to the presence of pilchard eggs.

The eggs and young stages of other commercially important fishes were taken, particularly of the stockfish (*Merluccius capensis*), which is very like the European hake. Since ripe and running stockfish were trawled in early autumn, it is not surprising that larvæ and post-larvæ were taken during this season (see drawings), but they also formed part of the spring plankton. Evidently the spawning season is prolonged, as with other members of this genus.

The material is not yet completely sorted, and it is likely to be some time before its implications are fully understood and a detailed account prepared.

NEWS and VIEWS

Presidency of the British Association, 1952: Prof. A. V. Hill, C.H., F.R.S.

The election of Prof. A. V. Hill to the presidency for 1952 of the British Association for the Advancement of Science, in succession to H.R.H. the Duke of Edinburgh, is timely in view of the fact that at the end of this year Prof. Hill resigns from the Foulerton professorship of the Royal Society—a chair which he has held with such distinction since 1926. Prof. Hill was Brackenbury professor of physiology in the University of Manchester during 1920–23, after which he was appointed Jodrell professor of physiology in University College, London. In 1926 he became Foulerton professor of the Royal Society, working at University College. When, in 1926, he ceased to be Jodrell professor in University College, the University of London appointed him honorary professor. His honorary professorship also expires at the end of this year under the age-limit, and the University has now conferred upon him the title of emeritus professor. Prof. Hill intends to continue his researches at University College, London, accommodation having been placed at his disposal through the courtesy of Prof. G. L. Brown, the present Jodrell professor. Also at the end of this year, the Biophysics Research Unit at University College, of which Prof. Hill has been such a distinguished head and which hitherto was financed by the Royal Society and the Rockefeller

Foundation, will come under the financial charge of the College and will be raised to the status of a Department, with Dr. B. Katz, at present reader in experimental physiology, as professor.

Prof. Hill was awarded the Nobel Prize for Physiology and Medicine in 1922, and the Copley Medal of the Royal Society in 1948. During 1935–45 he was a secretary of the Royal Society and during 1945–46 he was the Society's foreign secretary. This is not the place to deal with Prof. Hill's world-famed researches in physiology, especially biophysics, or to chronicle his many activities in connexion with scientific advancement and education, except perhaps to mention that he was member of Parliament representing the University of Cambridge during 1940–45.

Endeavour Prizes at the British Association

On August 9 at the British Association meeting in Edinburgh, H.R.H. the Duke of Edinburgh presented prizes to the winners in a scientific essay competition for young scientific workers less than twenty-five years of age. This was the second year of the competition, which was sponsored by *Endeavour*, a quarterly review of science published by Imperial Chemical Industries, Ltd. Altogether seventy-six essays were submitted, and the prize-winners (their ages shown in brackets) were as follows: *First Prize of Fifty Guineas*, B. C. Kilkenny (23), of Beaumont College, Old Windsor and New College, Oxford, and now a research student in the Physical Chemical Laboratory, Oxford, for an essay on "Biological Effects of Radiation"; *Second Prize of Twenty-Five Guineas*, J. H. Pantin (21) (the son of Dr. C. E. A. Pantin, president this year of the Zoology Section of the British Association), of Oriel College, Oxford, for an essay on "Animal Locomotion"; *Third Prize of Ten Guineas*, P. G. Garner (24), of Cambridgeshire High School for Boys and King's College, London, and now a research student in physical chemistry at King's College, for an essay on "Chromatography and its Possibilities"; *Special Prize of Five Guineas* (for a competitor under eighteen years of age), M. J. Sheridan (17), of Hornsey County School, for an essay on "Seaweeds and their Uses".

Use of Fuel and Power Resources

Mr. P. J. Noel-Baker, Minister of Fuel and Power, has appointed a committee to consider the use of resources of fuel and power in Great Britain. The terms of reference are: "In view of the growing demands for all forms of fuel and power arising from full employment and the rearmament programme, to consider whether any further steps can be taken to promote the best use of our fuel and power resources, having regard to present and prospective requirements and in the light of technical developments". The membership of the committee is as follows: Viscount Ridley, member of the former Fuel and Power Advisory Council (*chairman*); Mr. Lincoln Evans, general secretary of the Iron and Steel Trades Confederation; Mr. N. W. Gardiner, technical director of Huntley and Palmers, Ltd.; Sir Claude Gibb, chairman and managing director of C. A. Parsons and Co., Ltd.; Prof. W. R. Hawthorne, professor of applied thermodynamics, University of Cambridge; Prof. W. A. Lewis, professor of political economy, University of Manchester; Mrs. M. Mackintosh, tutor in sociology at Bedford College, University of London; and Miss M. R. Schofield, housing manager of Stoke Newington Borough Council.

I. G. Farben Central Laboratory Index

Technical information about chemical products marketed under trade names in Europe and America is available at the Technical Information and Documents Unit, Department of Scientific and Industrial Research, Lacon House, Theobalds Road, W.C.1. The information is contained in twenty-nine reels of microfilm and is a photographic facsimile of the I. G. Farben Central Laboratory Index. The index appears to have been compiled during the years 1933–43, although a few additional notes are dated 1946, and it comprises more than 57,000 cards. The information is given in alphabetical order under trade names and includes the chemical name of each product or its analysis, and its constitution and application. In addition, information about patents and literature reference is given. Most of the entries refer to dyestuffs, but the index also covers resins, plastics, detergents, wetting agents, waterproofing and emulsifying agents, textile assistants, rubber accelerators, cellulose esters, synthetic rubber, oil additives, tannins, insecticides, solvents, pharmaceutical products and other commodities. The index can be inspected at the Technical Information and Documents Unit (Chancery 4411) by appointment and no charge is made for inspection. Photo copies of entries may be ordered and purchased.

Odours of Minerals

An informative article on "The Odours of Minerals", by Dr. W. McCartney, has appeared in *The International Perfumer* (No. 3, 1951, pp. 7–10). The odours attributed to some solid bodies, which, having negligible vapour pressures, might be expected to be entirely odourless, are by no means imaginary, and have attracted attention since as early as 1798, when Fourcroy discussed the odours of metals. Later, in 1898, a study of the odours of a number of metals was described by Ayrton at a meeting of the British Association at Bristol; he concluded that the odours were not those of the metals themselves but of impurities and substances produced, for example, by human breath and perspiration. Later work has substantiated Ayrton's conclusions, and has demonstrated that metal surfaces can adsorb and tenaciously retain traces of organic compounds such as mercaptans and thio-ethers. Another aspect of the same phenomenon concerns natural minerals. The odours emitted on striking white pebbles and other minerals such as quartz, agate and flint have been found to be caused by organic impurities. These impurities may be present as bituminous inclusions or may be derived from dust, lichens, moss or algæ, or from earth or mud; but contamination by organic matter, imparted by contact with human hands, is one of the chief causes of such odours. Brief contact with human skin imparts this property; the impurity is very tenaciously retained, and can only be removed by such drastic treatment as ignition at a dull red heat; washing with alkali or brushing seem to be ineffective. Other types of mineral odours, the odours sometimes noticed by mountaineers in the neighbourhood of landslides and avalanches, may be caused by the frictional heating of rock matter containing traces of pyrites or vegetable matter.

Eelworm Pests of Mushrooms

A paper, "Eelworms (Nematodes) as Pests of Mushrooms", by Charles A. Thomas and George H. Mitchell, is reprinted in Bull. No. 22 of the Mushroom

Growers' Association (January 1951; obtainable from the Association at Yaxley, Peterborough; 5*s*.). It describes how eelworms belonging to the groups *Ditylenchus* and *Rhabditis* may damage mushroom beds by the destruction of mycelium, leaving bare patches, and by the distribution of disease-producing bacteria. They may be carried to the beds initially on the casing soil, but also persist between crops upon the bed boards. Satisfactory control has been obtained by heating the houses uniformly, after filling, to 140° F. for a day or more. Steaming the house for several hours after the temperature begins to fall helps with the sterilization of boarding. The temperature should not reach 150° F. or moulds may bring another kind of damage. Formaldehyde treatment is ineffective as a control, and chloropicrin has given variable results.

Prehistoric Cave Paintings in South Africa

The March issue of the *South African Archæological Bulletin* contains an article by J. R. Harding on his investigations at a rock-shelter site about six miles to the east of Bethlehem, Orange Free State. Some poor paintings occur, the most recent apparently being the figure of a Bush woman. The industries excavated range from Smithfield *C* without pottery to levels where pottery appears, to a latest Smithfield *C* with strong Bantu influence, with even some evidence of true Bushman occupation. It seems scarcely likely that any of the paintings are older than the industries unearthed, and none of these can be assigned to a very remote period. The paintings themselves are poor specimens and not well drawn.

Entomological Testing Methods

In 1948, the Entomology Subcommittee of the Chemical – Biological Coordination Center, U.S. National Research Council, obtained information on insecticide-testing from numerous laboratories and the results were distributed to participants. The Subcommittee planned to continue this successful survey. Recently, after discussions with the American Association of Economic Entomologists and others, it was decided that a book on testing methods in entomology would be more useful and, in April 1951, Dr. Harold H. Shepard, U.S. Department of Agriculture, was appointed editor. The book will include toxicological and screening methods used by entomologists in the United States and other countries and will contain descriptions of methods detailed enough to permit them to be duplicated. It will be published by the National Research Council and sold at cost price. Those who wish to participate in this project by furnishing descriptions of the test methods which they use should apply for forms to Dr. Raimon L. Beard, Chairman, Entomology Subcommittee, Chemical–Biological Coordination Center, National Research Council, 2101 Constitution Avenue, Washington 25, D.C.

Cartography of the Antarctic

Recent American and Norwegian work, as well as the discoveries of the German Swabenland expedition in 1939, are incorporated in a new map of the Antarctic by H. P. Kosack in *Petermanns Mitteilungen* (95, No. 2; 1951). The map, which is in blue and brown, is on a scale of 1 : 11,250,000, and shows surface and bathymetrical relief in 1,000-m. form lines. Notes in the margin give the location of the British, Argentine, Chilean and French stations. Names in the main follow the English usage; but there are many new German names in New Swabenland and American names in Marie Byrd Land and in the Ellsworth plateau. Accompanying this map is one on the scale of 1 : 4,000,000 of New Swabenland and adjoining territories between Coats Land and Princess Ragnhild Coast. A full and critical list of cartographical sources is given. Another article in the same number of this German publication, "Zur Frage der Namengebung in der Antarktis", by Dr. J. Georgi, gives the sources of German names in the Antarctic map with a full list of such names. This is most useful and should be done for all names in the Antarctic before there are no members left of the various expeditions who can supply the information. Already the origin of several German names of the 'nineties are untraceable.

The Chillingham Cattle

For thirty years prior to 1947 the strength of the famous herd of cattle in the park at Chillingham Castle in Northumberland had been fairly constant at about 35–40 head. After the severe winter of 1947, thirteen survived, of which eight were cows, five were bulls and none was young. For eighteen months or so no calf was born, and it was feared that the king bull might have become infertile; it was thought that this bull would have to be destroyed to save the herd from extinction. Fortunately, two bull calves arrived and, later, four heifers. The herd now consists of three bulls, seven cows, two bull calves and four heifer cows and now seems to be re-establishing itself. To help in the preservation of this valuable herd, which has almost certainly been at Chillingham Park since 1240, in 1939 an Association was formed. Those who wish to view the herd and apply for membership of the Association should write to the Secretary, Chillingham Wild Cattle Association, Ltd., Estate Office, Chillingham, Alnwick, Northumberland, for further information.

World Metallurgical Congress

A World Metallurgical Congress will be held in Detroit, Michigan, during October 14–19. It is expected that more than five hundred individuals from some twenty different countries will attend, in addition to American metallurgists. The Congress has the full support of the Economic Cooperation Administration of Washington, D.C. A technical assistance programme covering visitors from E.C.A. countries has been established at the request of the Organization for European Economic Cooperation. Foreign visitors are expected to arrive about September 15 and will spend approximately five weeks in the United States. During the first four, they will be divided into eight groups participating in a series of study tours to industrial, government and educational institutions to observe at first hand the scientific, industrial and educational advances that have taken place in the United States during the past few years. Dr. Zay Jeffries, of Pittsfield, Mass., retired vice-president of the General Electric Company, and a past president of the American Society for Metals, has been appointed director general of the Congress. Early in the Congress a comprehensive summary of raw materials of the world as they relate to the metal industry will be presented. Visiting authorities from various countries will discuss problems of conservation, utilization and substitution of strategic metals. The industrial study tours planned in connexion with the Congress are being arranged in eight categories of the metal industry: steel-making and refining; non-ferrous refining, rolling and fabrication (copper, brass, bronze, aluminium, magnesium); ferrous rolling, forging and hot work in steel mills and heavy industry; stamping, cold work, machining and finishing in lighter industry; heat treatment; welding and joining; inspection and testing; and research, engineering societies and universities. Information concerning the World Metallurgical Congress can be obtained from the Secretary, American Society of Metals, 7301 Euclid Avenue, Cleveland, Ohio.

Symposium at Delft on Abrasion and Wear

A symposium on abrasion and wear, organized by Rubber-Stichting on the occasion of the opening of a new building at Delft, will be held during November 14–15. The first day will be devoted to general aspects of the subject, including problems connected with friction and lubrication, and the second day to the applied side, that is, the abrasion and wear of metals, plastics, rubber and other materials. The symposium will be international in scope, in that a number of foreign workers will be participating, some of whom will be reading papers; the official languages of the symposium will be English and French. In conjunction with the meeting an exhibition of apparatus for measuring abrasion and wear has been arranged. Admittance to the symposium will be free. Further details can be obtained from the secretary of the organizing committee, Dr. H. C. J. de Decker, c/o Rubber-Stichting, P.O. Box 66, Delft.

Colonial Service Appointments

The following appointments in the Colonial Service have recently been announced: A. K. Briant (senior agricultural officer, Zanzibar), director of agriculture, Zanzibar; J. W. D. Goodban (agricultural officer, Nigeria), director of agriculture, British Honduras; C. E. Johnson (agricultural officer, Northern Rhodesia), chief agricultural officer, Northern Rhodesia; C. J. MacK. Krige (senior agricultural officer, Northern Rhodesia), chief agricultural officer, Northern Rhodesia; J. Wright, whose appointment as assistant director of agriculture, Nigeria, was previously announced, re-transferred to his former post of deputy director of agriculture, Jamaica; M. E. Dommen (senior assistant conservator of forests, Nigeria), conservator of forests, Nigeria; W. Crocker (senior assistant, Department of Agriculture, Sarawak), assistant agricultural officer, Sarawak; R. A. Sutton (chemist, Government Chemist Department, Tanganyika), geo-chemist, Geological Survey Department, Tanganyika; F. B. Brown, agricultural officer, Federation of Malaya; C. Purvis, geneticist, Oil Palm Research Station, Nigeria; L. P. Adams, staff surveyor, Kenya; Lieut.-Colonel J. D. Daly, veterinary officer, Federation of Malaya; Dr. R. A. Webb, soil scientist, Gambia.

Announcements

Lord Bruce of Melbourne, formerly Australian High Commissioner in London, has been elected the first chancellor of the Australian National University, Canberra.

Dr. E. U. Condon, director of the U.S. National Bureau of Standards, is resigning as from September 30. It is reported that Dr. Condon is to join the Corning Glass Company as a technical director.

Prof. N. V. Sidgwick, formerly professor of and reader in chemistry in the University of Oxford, has been elected an honorary life member of the Faraday Society in recognition of his outstanding services to physical chemistry and to the Society.

Sir Archibald Gill, engineer-in-chief of the Post Office, is to retire on October 1; he will be succeeded by Dr. W. G. Radley, who is at present a deputy engineer-in-chief.

Mr. E. K. Inall, who until recently was a member of the research staff of Associated Electrical Industries, Ltd., Aldermaston Court, Berks, has been appointed a Research Fellow of the Australian National University, Canberra. He will work in the Department of Nuclear Physics under the direction of Prof. E. W. Titterton.

In order to ensure that the fullest use is made, in the interests of the aircraft industry in Great Britain, of all published scientific and technical information concerning aeronautics, Aslib is establishing an Aeronautical Information Study Group, the inaugural meeting of which is to be held on September 27 at the Royal Aircraft Establishment, South Farnborough, Hants. All those interested in the formation of such a Group should write, not later than September 10, to Mr. Leslie Wilson, director of Aslib, at 4 Palace Gate, London, W.8.

The Research Fund of the Chemical Society provides grants for the assistance of research in all branches of chemistry. About £700 per annum is available, the income being derived from a donation of the Worshipful Company of Goldsmiths, from the Perkin Memorial Fund, and from other sources. Applications for grants will be considered in November next and should be submitted on the appropriate form, to be obtained from the General Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1, not later than November 1, 1951.

The fifth congress of the International Scientific Film Association will be held in the Municipal Museum, The Hague, during September 15–22. At the congress the general assembly of the Association will take place, together with meetings of the permanent committees dealing with medical, research, technical and industrial films, as well as a Festival of Scientific Films. Further information can be obtained from the Secretary, Scientific Film Association, 4 Great Russell Street, London, W.C.1.

The following lectures of the Royal Aeronautical Society have recently been announced. The thirty-ninth Wilbur Wright Memorial Lecture will be given by A. E. Raymond, of the Douglas Aircraft Corporation, California, at 6 p.m. on September 10 at the Royal Institution, 21 Albemarle Street, London, W.1, his subject being "The Well-Tempered Aircraft". The seventh British Commonwealth and Empire Lecture will be given by Air Vice-Marshal Sir L. M. Isitt, of New Zealand, at 6 p.m. on October 4 at the Institution of Civil Engineers, Great George Street, London, S.W.1, his subject being "Air Transport in New Zealand and the South Pacific". Further details can be obtained from the secretary of the Society, A. M. Ballantyne, at 4 Hamilton Place, London, W.1.

Erratum.—In *Nature* of June 30, p. 1060, it is stated that the chairmen of the four Groups of the Physical Society are for the period 1950–51; this should read 1951–52. Further, the chairman of the Colour Group for this period is Dr. T. Vickerstaff.

College of Science PHYSICS Dept.

THERMAL CONDUCTIVITY OF DIELECTRIC CRYSTALS: THE 'UMKLAPP' PROCESS

By Dr. R. BERMAN, Prof. F. E. SIMON, C.B.E., F.R.S., and Dr. J. WILKS
Clarendon Laboratory, Oxford

BECAUSE of the experimental difficulties in obtaining temperatures over the whole range below 100° K., measurements on thermal conductivity have not hitherto been sufficiently extensive to reveal all the characteristics of the conductivity/temperature relationship. We have recently measured the thermal conductivities of several very different dielectric crystals over a wide range of temperatures: Fig. 1 shows the conductivities of single crystals of quartz, sapphire[1], and diamond[2], and Fig. 2 gives values for crystals of solid helium at different densities measured over a smaller temperature range[3]. (We may note that our results on diamond, made on a large, well-cut specimen, confirm Eucken's belief that his own results[4] were unreliable.) It can be seen that all the crystals referred to in Fig. 1 behave similarly and all have a pronounced maximum; more recent measurements have shown that there is also a maximum in the curves for helium at lower temperatures. These results suggest that the thermal conductivities of all pure dielectric crystals behave in the same general way and enable us to discuss the underlying internal processes.

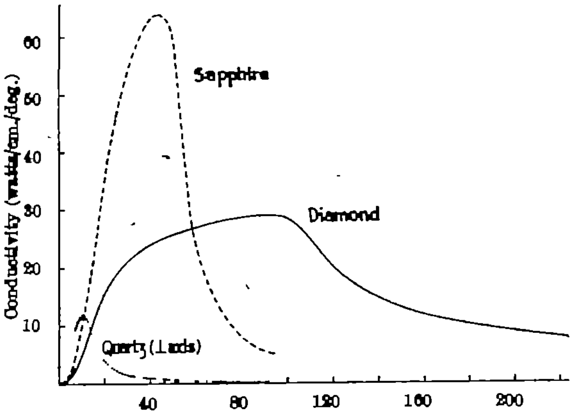


Fig. 1. Thermal conductivities of quartz, synthetic sapphire and diamond

Some years ago, de Haas and Biermasz[5] made measurements on crystals of quartz, potassium chloride and potassium bromide at low temperatures, and together with Casimir[6] demonstrated that in the region where the conductivity falls with temperature the flow of thermal energy is limited by its being scattered at the walls of the crystal. This is the so-called 'size effect' which results in the measured thermal conductivity becoming proportional to the smallest dimension of the specimen and to the cube of the absolute temperature. As a result of this discovery, attention was directed away from the region where the conductivity rises as the temperature falls, and no systematic measurements were made there. While the present results give some additional data on size-effect phenomena, which will be published elsewhere, their main interest is in throwing some light on the intrinsic properties of bulk crystals.

The foundations of all discussions on thermal conductivity were laid down by Debye[7], who treated the atomic vibrations of a solid as an assembly of elastic waves in a continuum. He derived the general formula for conductivity:

$$\kappa = \tfrac{1}{3}lCv, \tag{1}$$

where v is the group velocity of the waves (the velocity of sound) and C the thermal capacity per unit volume. The remaining quantity, l, the mean free path, is the distance which the waves travel before being attenuated by a factor e. He showed that this expression leads to the observed relation $\kappa \propto 1/T$ when the temperature is high enough for C to be taken as constant; but it gives no explanation of the behaviour at lower temperatures.

Later, Peierls[8] treated a crystal as a lattice rather than as a continuum; at high temperatures his theory also predicts that the thermal conductivity varies as $1/T$; but at low temperatures it leads to a relation of the form $\kappa = QT^{\nu}\exp(\theta/2T)$, where Q is some constant, ν is of order unity and θ is the Debye specific heat parameter. (Provided that the conductivity is not limited by size effect, this implies that it should approach infinity at absolute zero.) As the processes responsible for the form of this law are not widely understood, it may be useful to discuss them in some detail.

In a large pure crystal free from impurities, cracks and strains in its structure, the scattering of thermal waves will only be caused by collisions between the waves themselves. Peierls treated these by quantizing the sound waves into quanta of vibration or phonons

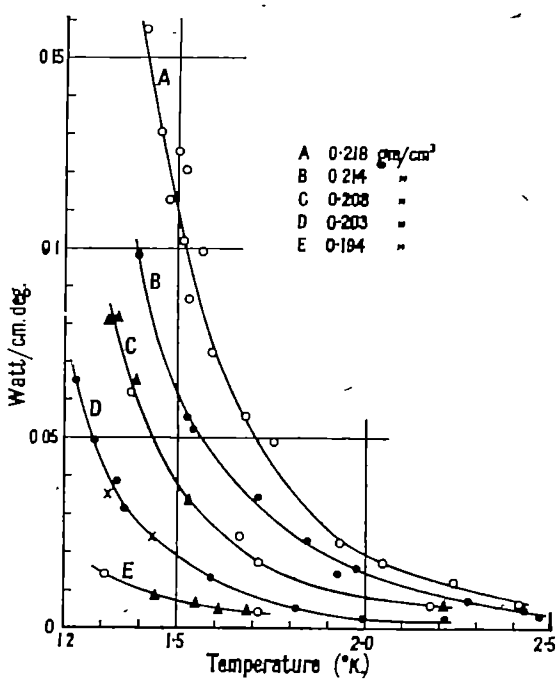

Fig. 2. Thermal conductivity of solid helium at constant density

and then finding the conditions for the phonons to interact. It turns out that the only collisions of importance are three-phonon processes in which two phonons coalesce to give one, or one splits up to give two. Such collisions are shown to be possible if:

$$\omega_1 + \omega_2 = \omega_3, \tag{2}$$

$$\bar{K}_1 + \bar{K}_2 = \bar{K}_3, \tag{3}$$

where the ω's are the angular frequencies and the $\bar{K}$'s the wave numbers associated with the phonons. These conditions correspond to the conservation laws for energy and momentum. Equation (2) states that after a collision the resulting wave or waves are still carrying as much energy as before, while equation (3) implies that this energy is still flowing in the same direction. Hence, no impedance to the flow of energy is introduced by these collisions; that is, they do not give rise to any thermal resistance.

Peierls also showed that collisions are possible if

$$\omega_1 + \omega_2 = \omega_3, \tag{2}$$

$$\bar{K}_1 + \bar{K}_2 = \bar{K}_3 + \frac{2\pi\bar{\varepsilon}}{a}, \tag{4}$$

where a is the lattice constant and $\bar{\varepsilon}$ is a unit vector which can take up any one of six orientations parallel to the axes of the crystal (for simplicity Peierls treats a cubic lattice). To put it colloquially, equation (4) means that for some collisions between phonons 'momentum is not conserved'. More precisely, we can say that though equation (2) implies that there is no energy change resulting from collision, equation (4) states that the direction of flow of this energy will be altered. Although there is some correlation between the initial and final directions of flow (as given by equation (4)), $\bar{\varepsilon}$ can take up any one of six directions, so that the final result is much the same as if the waves were scattered at random. Hence such collisions will impede the flow of energy and give rise to a thermal resistance.

Peierls has named this type of collision an 'Umklapp' process, which can perhaps best be translated as a 'flap-over' process; at a collision the wave number vector 'flaps over' and takes up a new position. Umklapp processes, or U-processes, result from the periodicity of the lattice: they would not occur, for example, in a continuum. They come about because of the possibility of interference effects between the phonons and the lattice by which the lattice can transfer momentum between itself and the phonons. It is as if phonons can suffer Bragg reflexions from the lattice; and equation (4) may be taken to mean that because the lattice is perturbed by the mode $\bar{K}_2$, conditions are favourable for the phonon $\bar{K}_1$ to suffer Bragg reflexion into the phonon $\bar{K}_3$.

If a U-process is to take place at all, we see from (4) that

$$\bar{K}_1 + \bar{K}_2 > \frac{2\pi\bar{\varepsilon}}{a}.$$

This implies that phonons must have a certain minimum energy before they can 'umklapp', and Peierls shows that, as a rough criterion, this minimum energy may be taken as $k\theta/2$, where k is Boltzmann's constant. Hence the probability of U-collisions will contain the term $\exp(-\theta/2T)$; and when T is small the variation of this exponential term will mask any temperature-dependent term of the form T^{r}.

Although Peierls derives the thermal conductivity without using the concept of mean free path, it seems a convenient parameter with which to characterize a given scattering process. Therefore we introduce λ, which we define as the mean distance travelled by phonons between collisions which produce scattering. Since the waves in Debye's theory have now been replaced by quanta, we rewrite equation (1) as

$$\kappa = \tfrac{1}{3}\lambda C v \tag{5}$$

by analogy with the kinetic theory of gases. In particular, for single crystals free from impurities, cracks and mosaic structure, the mean free path is limited only by U-collisions, so that:

$$\kappa = \tfrac{1}{3}\lambda_U C v, \tag{6}$$

where λ_U is the mean free path for U-collisions. It is, of course, important to note that this concept of mean free path is a more complex one than that met with in gas kinetics, because the probability of U-processes depends on the polarization of the colliding phonons as well as on their energy.

Values of λ_U for several crystals, including solid helium, have been calculated from equation (6) by using the measured values of the thermal conductivity and specific heat; the values of the velocity of sound are derived from the corresponding specific heat by Debye's theory. Fig. 3 shows these values plotted against θ/T for artificial sapphire, diamond and solid helium, θ being obtained from specific heat measurements. It is clear that to a fair approximation, over a considerable range, we may write

$$\lambda_U = A\exp(\theta/bT), \tag{7}$$

where A is a constant depending on the crystal and b has a value slightly greater than 2 (2·3 for helium, 2·7 for diamond, 2·1 for sapphire). The fact that we obtain this relation both supports Peierls' theory and also suggests that any thermal resistance due to imperfections in the crystals is small compared with the resistance due to U-processes. Unfortunately, it is not possible to calculate the values of A to be expected on Peierls' theory.

The measurements which have been made on crystals of solid helium are of particular interest as the density of the helium can be changed considerably by using quite moderate pressures, and this makes a very big difference to the thermal conductivity. Although the conductivities at different densities differ greatly (Fig. 2), values of λ_U which have been calculated at temperature intervals of 0·1° for all five densities lie approximately on the same curve. Thus, in helium the number of U-collisions is primarily a function only of θ/T.

We may note here that exact agreement with Peierls' theory cannot be expected, because the behaviour of real crystals only approximates to that of Debye-type models. For example, the specific heat of solid helium at these low temperatures does not vary exactly as T^3, and so there is no unique value of θ corresponding to each density. The values of θ used in Fig. 3 were obtained from the known specific heat by using Debye's formula $C = 464\,(T/\theta)^3$ cal./gm. atom/degree. This is certainly justifiable as a first approximation, since the variation in θ due to the density changes is about ten times as great as the variations due to the temperature changes. The position with sapphire and quartz is also complicated, because these have two or more atoms of different

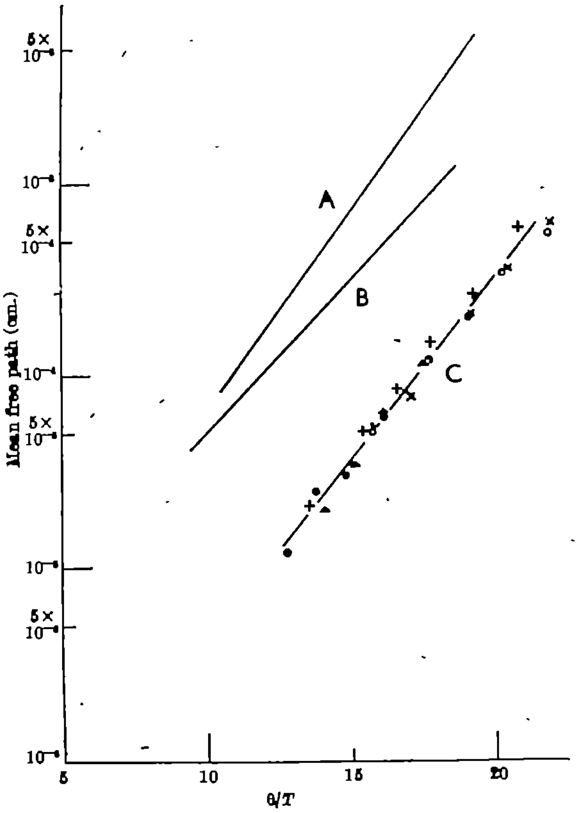

Fig. 3. Mean free path for U-collisions as a function of θ/T. A: synthetic sapphire ($\theta \simeq 980$); B: diamond ($\theta \simeq 1{,}840$); C: solid helium (θ, 28–35). For solid helium the densities are 0·218 (×); 0·214 (○); 0·208 (+); 0·203 (▲); 0·194 (●) gm./cm.^{3}

mass in the unit cell and so again they cannot conform to Debye's theory. Quartz, too, is difficult to treat, as the crystal is strongly anisotropic and the conductivities in directions along, and perpendicular to, the axis differ by a factor of about 2; so quartz has not been included in Fig. 3. Even so, the general behaviour of these thermal conductivities is similar to that in other crystals, as may be seen from Fig. 1.

The picture we have presented so far has to some extent been over-simplified; for example, Peierls[8] pointed out that phonons corresponding to transverse and longitudinal waves behave differently in collision processes. Klemens[9] has recently treated the statistical equilibrium of phonons and shown that it is also necessary to consider collisions which conserve momentum because, while they do not contribute directly to the thermal resistance, they may change the polarization of a phonon and thus render it more susceptible to a U-collision. He derives an expression for the thermal conductivity which is of the same form as Peierls' expression, save that he gives $\nu = 1$. As the term $\exp(\theta/bT)$ is very sensitive to the value of b, it is unfortunately impossible to verify that the power of T in the equation is really 1 and not, say, 2 or zero, particularly as none of the crystals is theoretically ideal. Obviously it would be desirable to make more measurements on crystals with a simple structure; but in practice there are not many suitable crystals available, particularly as the conductivity of ionic crystals is very sensitive to the effect of scattering by impurities, which would mask U-type collisions.

It is interesting to note that for each crystal the maximum in the thermal conductivity occurs at a temperature of about $\theta/20$. At first sight this maximum might be expected where λ_U first becomes limited by the size of the crystal. As the specimens were in the form of rods a few millimetres in diameter, this criterion gives $\lambda \sim 0{\cdot}1$ cm. Therefore, since λ_U is given primarily by θ/T, it is to be expected that the maximum would occur at a particular value of this parameter. Although we find this to be so, the value of the mean free path calculated by substituting the value of the maximum conductivity into equation (5) is an order of magnitude less than the size of the crystals. Klemens, in his more detailed treatment[9], has shown that in the region near the maximum where both U-processes and scattering by the walls play an appreciable part, some such effect is to be expected; but it does not appear sufficient to account for the large reduction in mean free path which is observed.

There is, in addition, the possibility that the mean free path may also be limited by departures from complete regularity in the crystal lattice[10]; the effect of one particular form of mosaic structure has been treated by Pomeranchuk[11]. It seems that it would introduce a thermal resistance which would again account for the reduction of the conductivity near the maximum, so that not until the lowest temperatures, where even this resistance is negligible, should the mean free path become comparable with the smallest dimension of the crystal. This is in agreement with our experiments and those of de Haas and Biermasz. We may note that this reduction in the magnitude of the mean free path near the maximum does not have much effect on the position of the maximum, as λ_U varies very rapidly in this neighbourhood. In particular, the very flat top on the curve for diamond suggests that some such process as this may be taking place.

Values of λ_U for high temperatures are not given in Fig. 3, because the exponential is not varying so rapidly in this region and, owing to the other temperature-dependent terms derived by a more detailed treatment, the simple relation (7) no longer holds. Those measurements which we have made at higher temperatures ($\theta/T < 10$) suggest that, at very high temperatures ($\theta/T \rightarrow 0$), λ_U tends to a value of a few angstroms, a distance of the order of the atomic spacing. This is in agreement with other work done at relatively high temperatures. For example, in potassium chloride[12], one of several substances for which data on single crystals are available, we find that the mean free path at 0° C. ($\theta/T = 0{\cdot}8$) is only a small number of lattice spacings.

Over the range of θ/T between 10 and the maximum, we may write $\lambda_U = A\exp(\theta/bT)$, where A varies from 6×10^{-8} cm. for solid helium to $1{\cdot}4 \times 10^{-6}$ cm. for diamond. In order to relate the constant A to some property of the crystal, we recall (Debye[7], Peierls[8]) that if the forces between the atoms in a crystal were perfectly harmonic, there would be no interactions between the various modes of vibration (that is, no collisions between phonons); thermal equilibrium could never be established and it would be impossible to define a thermal conductivity. Interactions between modes, or collisions of phonons, are only possible if the forces are anharmonic, and it is reasonable to suppose that the greater the anharmonicity the greater the number of collisions. Of course, once collisions occur, their temperature-dependence includes the exponential term; but their absolute number is given by A and must depend in some way on the anharmonicity of the inter-atomic forces. In principle, it is possible to derive A by perturbation theory from the anharmonicity as measured by the second pressure derivative in the equation of state; for example, a solution of a comparatively simple problem of this type has been given by Van Vleck[13]. Unfortunately, the difficulties of solving the relevant equations for the general problem of thermal conductivity appear to be very great; also it would not be easy to get the necessary experimental data for crystals as hard as sapphire. The density of helium, however, may be changed quite easily, and we hope that it may be possible to correlate its thermal conductivity with measurements on its compressibility.

To sum up, we may say that the thermal conductivities of pure dielectric crystals follow a common pattern. At sufficiently high temperatures they vary as $1/T$; then at lower temperatures the conductivities increase more rapidly until they are limited by size effect and fall off towards zero. The shape of the conductivity/temperature curve is to a fair approximation determined only by θ, the specific heat parameter. It is, of course, true that the values of the conductivity in the U-region also depend on the constant A, but as may be seen from Fig. 3 this lies within relatively narrow limits. Thus, while the magnitudes of the thermal conductivities of the different crystals vary greatly (the lowest value measured was 2×10^{-4} watt units for helium at 2° K. and the highest 60 watt units for sapphire at 50° K.), they can all be deduced, at least to an order of magnitude, once the specific heat parameter is known.

THEORETICAL ASPECTS OF SUPERCONDUCTIVITY

Crystal Structure and Superconductivity

THE prediction that it is the interaction between electrons and lattice vibrations[1] which is responsible for the establishment of the superconductive state has been verified by the discovery of the isotope effect[2]. Theoretically, for a metal to be a superconductor a condition regarding the strength of this interaction has to be fulfilled. This condition requires (see ref. 1*a*, equations (3.19) and (6.8)) that a parameter which depends on the number ν of free electrons per atom must exceed a certain value. This parameter is proportional to $(4\nu)^{1/3}$ if $4\nu < 1$ and proportional to $1/(4\nu)^{1/3}$ if $4\nu > 1$. On the assumption that other quantities entering into it are independent of ν, an optimum for the attainment of superconductivity is reached if $\nu = 1/4$.

The number ν of free electrons of a metal depend on its Brillouin zone structure, which in turn i determined by the lattice structure. Since each zon contains sites for two electrons per unit volume $\nu = 1/4$ means either nearly empty, or nearly full zones. This is actually the case for most superconductors, as was remarked some time ago by Bor and Cheng[3].

The result $\nu = 1/4$ was derived on the assumptio of free electrons. It holds, however, whenever th energy of the electrons is proportional to the squar of the wave-number. For some structures this ma not be so, and thus a modification of the exact valu of ν is required, although the above qualitativ statement regarding the occupation of zones wil probably hold in most cases. Superconductivity and Effective Mass of Electrons

SOME time ago, Bardeen[1] suggested that a very small effective mass of electrons would lead to superconductivity. Later he found that the theory of the interaction between electrons and lattice vibrations[2] actually yields such a small effective mass[3]. I wish to show here, however, that small effective mass alone leads always to normal behaviour. Even though a state with non-penetrating magnetic field may be relatively stable[3], the normal state if it exists has always the lower Gibbs free energy, provided that no other than magnetic interaction between electrons is considered. Although the small effective mass is no doubt an important property, it is imperative in the presence of a magnetic field to consider the change of interaction between electrons and the vibrational field in order to obtain superconductivity, as has been shown recently[4].

To prove that without this the normal state exists (and hence is stable), let us review the results of the Landau–Peierls theory[5] of the diamagnetism of a gas of free electrons. Here the energy increase due to the presence of an external homogeneous magnetic field H_0 is calculated, based on a Hamiltonian:

$$\mathcal{H}_0 = \sum_k (\mathbf{p}_k - \frac{e}{c}\mathbf{A})^2/2m^*, \tag{1}$$

where m^* is effective mass, $\mathbf{A}$ is the vector potential and the sum extends over all electrons. The result per unit volume is found to be

$$\frac{1}{2}\,|\,\chi_0\,|\,(\text{curl }\mathbf{A})^2, \tag{2}$$

where the quantity $|\chi_0|$ is expressed in terms of various parameters. In particular, $|\chi_0| \rightarrow \infty$ if $m^* \rightarrow 0$. On the other hand, if χ is the magnetic susceptibility of a substance, its energy increases by $\frac{1}{2}|\chi|H_0^2$ if brought into the field, provided that $|\chi| \ll 1$. Hence, in this case χ_0 is equal to the magnetic susceptibility χ. Now since the permeability

$$\mu = 1 + 4\pi\chi = 1 - 4\pi|\chi| \tag{3}$$

must always be positive, then $|\chi| < 1/4\pi$.

It would be wrong to apply the result $\chi \simeq \chi_s$ to the case $m^* \rightarrow 0$ and thus derive a contradiction of the condition $|\chi| < 1/4\pi$. For in this case the Hamiltonian is

$$\mathcal{H} = \sum_k (\mathbf{p}_k - \frac{e}{c}\mathbf{A}_k)^2/2m^* + U_{int}; \tag{4}$$

where U_{int} represents the magnetic interaction energy between electrons, and $\mathbf{A}_k$ is the macroscopic vector potential at the position of the k-th electron diminished by the contribution to $\mathbf{A}_k$ of this electron. This latter is negligible so long as the radius of the classical orbit is large compared with the distance between neighbouring electrons. Hence,

$$\text{curl } \mathbf{A} = \mathbf{B} = \mu\mathbf{H}, \tag{5}$$

where $\mathbf{H}$ is the macroscopic field. Using (4), (2) and (5), the energy increase per unit volume is now given by

$$U = \frac{1}{2}|\chi_s|\mathbf{B}^2 + \bar{U}_{int} \tag{6}$$

where the bar indicates formation of the expectation value.

Expression (6) has to be equated to the energy increase U_m (per unit volume) obtained with the help of the macroscopic theory in terms of χ. Both U_m and U_{int} depend on shape, but the resultant value of χ is, of course, independent of shape. For this reason the simplest procedure is to consider a diamagnetic slab between the poles of a permanent magnet. The value of $\mathbf{B}$ is then the same as in the absence of the slab. Hence $U_{int} = 0$ and $U_m = (HB - B^2)/(8\pi)$. This expression must be equal to (6), which now is equal to $\frac{1}{2}|\chi_s|B^2$. Thus, using (3) and (5), we find

$$\left(\frac{1}{\mu} - 1\right)\frac{1}{8\pi} = \frac{1}{2}|\chi_s| \text{ or } \chi = \mu\chi_s. \tag{7}$$

Hence,

$$|\chi| = \frac{|\chi_s|}{1 + 4\pi|\chi_s|} < \frac{1}{4\pi}, \tag{8}$$

so that no contradiction to the condition $\mu > 0$ can occur, that is, the normal state exists.

Finally, to show that the result is actually independent of shape, consider a diamagnetic needle parallel to the direction of field. In this case $U_m = \frac{1}{2}|\chi|H^2$, because H is now equal to the field in the absence of the body. U_{int} is the self-energy per unit volume of a needle-shaped magnet with polarization $(B - H)/(4\pi)$; that is, $U_{int} = (B - H)^2/(8\pi)$. Equating U_m to U leads to the previous result (7). Specific Heat of Metals at Low Temperatures

The interaction in a metal between the lattice vibrations and the conduction electrons has been shown by Fröhlich[1] to lead, if sufficiently strong, to the superconductive state. If too weak for this, it can lead to modifications in the properties of the normal state at low temperatures. In suitable circumstances, for example, this S-interaction can lead to a peak in the specific heat at a few degrees absolute.

It has been shown by Fröhlich that if a certain factor, f, depending on the strength of the interaction, is greater than unity, the ordinary spherical distribution of electrons in momentum space is not the one of lowest energy at the absolute zero of temperature. For normal metals, $f < 1$ and the spherical distribution is, in fact, stable.

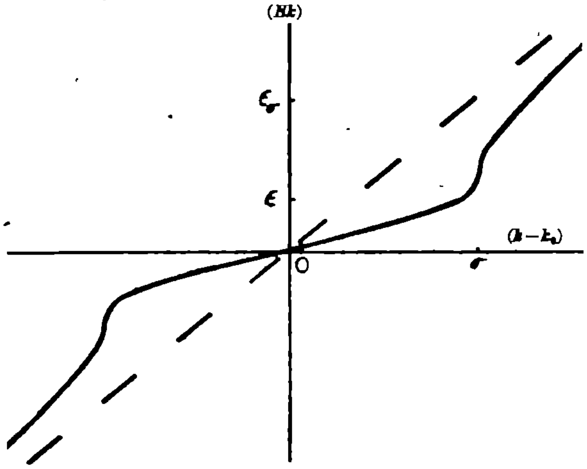

Fig. 1

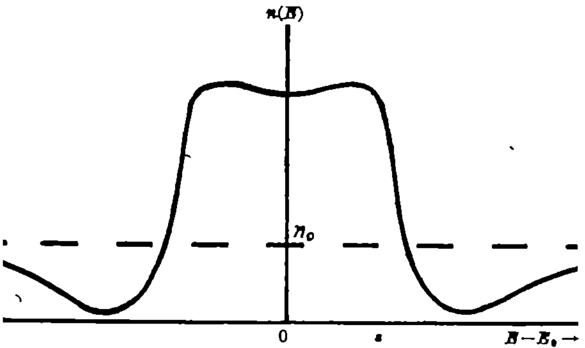

Fig. 2

The energy of an electron near the surface of the distribution at absolute zero is shown as a function of wave number in Fig. 1 for a possible normal state. The corresponding energy-level density is shown in Fig. 2. The broken lines correspond to the case $f = 0$ (or neglect of the S-interaction).

It is intended to discuss the properties of the superconducting state in a later communication, so we confine ourselves here to the case $f < 1$. The energy-level density, $n(E_0)$ at E_0, the edge of the filled region at the absolute zero, is then given by

$$\frac{n(E_0)}{n_0} = \frac{1}{1 - f}\ (f < 1). \tag{1}$$

The specific heat as a function of temperature will have the form shown in Fig. 3 for several values of f,

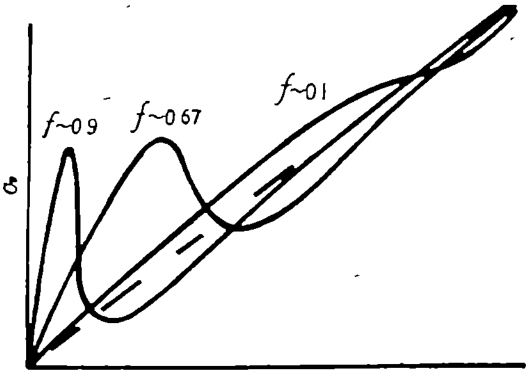

Fig. 3

the ratio of the slopes at $T = 0$ and $T = \infty$ being given by (1). The total energy due to the peak is, of course, of the same order of magnitude as the energy-difference of a superconductor in the normal and superconducting states at absolute zero.

Anomalous peaks of this energy have been observed in the specific heats of sodium[2] and beryllium[3], at about 7° and 11° respectively. The experimental results, however, do not show the linear increase at small temperatures given in Fig. 3, and it is thought that this may indicate an inadequacy in the description of states near the ground-state, a question which arises also in our investigation of the thermal properties of the superconducting state itself.

It is simple to estimate the energy content, ΔE, of the anomalous hump in the specific heat. From Fig. 2, and equation (1),

$$\Delta E \sim \tfrac{1}{2}\,(n(E_s) - n_s)\,\varepsilon^2 = \tfrac{1}{2}\,\{f/(1-f)\}n_s\,\varepsilon^2.$$

Now $\varepsilon = (1-f)\,\varepsilon_\sigma$, where $\varepsilon_\sigma = 2(\sigma/k_s)\zeta = kT_\sigma$, say, ζ being the Fermi energy, and if σ_s is the wave number of an electron moving with the velocity of sound, $(\sigma_s/\sigma)^3 = 4\nu$ (if $4\nu > 1$), where ν is the number of free electrons per atom (see equation (3.4) of ref. 1). From equation (2.7) of the same paper, we then see that $T_\sigma = \theta_D$, the Debye temperature. In the free-electron approximation we have, for one gram molecule:

$$kn_s = \tfrac{3}{2}\,\nu R\zeta^{-1},$$

so that

$$\Delta E \sim \tfrac{3}{4}\nu f(1-f)\,RkT_\sigma{}^2\zeta^{-1}. \qquad (2)$$

The peak containing this energy occurs at a temperature about $T' = \tfrac{1}{2}(1-f)T_\sigma$.

Using values appropriate to sodium, $\theta_D = 150°$, $\zeta = 3\cdot1$ eV., and $\nu = 1$, we must take $f \simeq 0\cdot9$ to make $T' \simeq 7°$ K., and (2) then gives $\Delta E \sim 0\cdot11$ calories, about equal to the value estimated from the experimental curve published by Pickard and Simon.

In the case of beryllium, $\theta_D \simeq 1{,}000°$, but the free-electron approximation cannot readily be applied since there are two zones nearly filled. It would be expected in this case that $T_\sigma \lessdot \theta_D$, but an estimate of ΔE on the lines of that for sodium would have little meaning.

My thanks are due to Prof. H. Fröhlich for many stimulating discussions, and to the Australian National University for the award of a travelling scholarship. [June 9.

A METHOD FOR MAKING ACCURATELY REPRODUCIBLE MASKS OF THE HUGGINS TYPE

By BARTON HOWELL, CARL J. CHRISTENSEN
AND
DAN McLACHLAN, Jun.
Departments of Physics and Ceramics, University of Utah

IN 1929 Bragg[1] described a method for the photographic summation of Fourier series by the addition of the proper patterns of light and dark bands. Huggins[2] in 1941 showed how this method could be improved in accuracy and speed by the use of a previously prepared set of masks, and in 1944 Huggins[3] published a number of illustrations of projected crystal structures produced by means of his masks. In Huggins's first paper[2], he described the photographic procedure that was followed in producing a sinusoidal transparency across the masks perpendicular to the light and dark bands. This procedure involved making what was called mask *A*, from which a second mask *B* was made, before producing the final masks for the Fourier summations. These two preliminary masks were necessary in order to compensate for the non-linearity in response of photographic material to light; and also because of this lack of linearity, no set of finished masks could be used as a master in making further copies of the masks.

The present investigation is based on the knowledge that much of the modern work in photographic reproduction is accomplished by using a master which has only two tone values, white and black, and in which the visual illusion of the various shades of grey is produced by the relative areas occupied by the discrete portions of white and black. This variation in area is usually accomplished by varying the size of the regularly spaced dots. However, in view of the difficulty in getting a perfectly sinusoidal distribution of sizes of black dots across a master figure, it was thought best to make the black areas them-

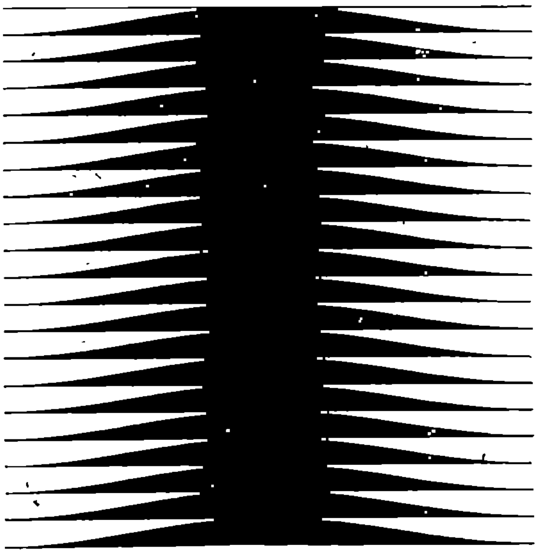

Fig. 1. Unit of pattern for assembling the master figures

selves vary in shape sinusoidally. Fig. 1 shows a unit of area used to build up the master figure. Each black streak in Fig. 1 obeys the equation

$$\omega = \omega_0 \left(1 + \sin \frac{2\pi n x}{L}\right),$$

where ω is the width at any distance, x, from the left-hand edge, ω_0 is the maximum width, and L is the length of the streak.

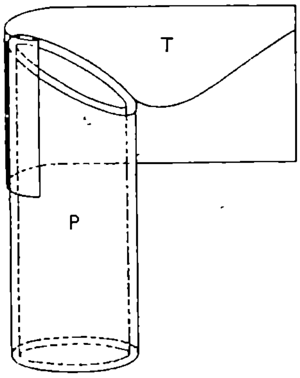

Fig. 2 Manner of making a template for drawing sine curves

Since it is very difficult to plot, from trigonometrical tables, these sinusoidal curves sufficiently accurately for this work, a template was made by the procedure shown in Fig. 2. A piece of 5-mill shim brass T is wrapped about a pipe P with a bevelled end. The inside of the shim brass is marked against the bevelled end of the pipe with a sharp metal scribe. When the brass is unwrapped from the pipe, a sine curve is apparent; and by cutting the brass on the scribed line, the template is ready for making curves and filling in with ink to produce Fig. 1.

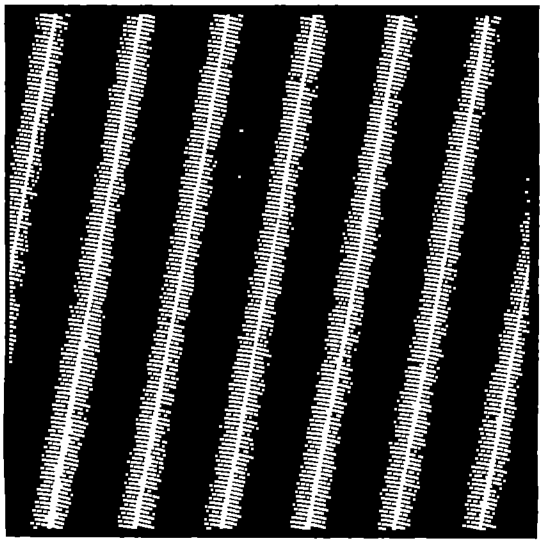

Fig. 3. Example of finished mask, showing the $6\bar{1}$ term

Fig. 3 shows the $6\bar{1}$ mask. Masks up to h and k values of 10 have been prepared and are available through the Universal Microfilming Corporation (277 6th Avenue, Salt Lake City 3, Utah). When these masks are used in the usual manner or in the multiple projector[4], the details of the white and black streaks are lost and a sinusoidal effect of dark and light bands is produced by out-of-focus projection.

APPLIED ELECTRONICS

THE exhibition of electronic devices which was held at the Manchester College of Technology during the last week of July was the sixth, and by far the largest, of the annual displays organized by the North-West Branch of the Institution of Electronics. The Exhibition, planned as part of the City's contribution to the Festival of Britain activities, included a number of special features in addition to the usual trade displays of production models of electronic equipment. The research section, in which applications of electronics were on show in the 'string and sealing-wax' stage, was particularly interesting; and there were a number of 'guest' exhibits which, in addition to being excellent examples of applied electronics, were also of high entertainment value. Film shows and a series of lectures on specific problems were also part of the programme.

In the space allowed, it would be impossible to describe all the exhibits which were of special interest, and it must be pointed out that the particular devices selected for mention here are not necessarily of greater merit than the rest but are simply those which had the greatest personal appeal to the writer.

Of the 'guest' exhibits, perhaps the most impressive was the 'Electrone' displayed by the John Compton Organ Co., Ltd. This attracted a lot of attention as it was a smaller version of the instrument to be installed in the Manchester Free Trade Hall. The console of the instrument is completely orthodox; the stops, pistons and manuals are identical with those to be found on a modern pipe organ, and in fact no additional knowledge or skill is required by the player than would be required for playing an equivalent pipe organ. The tones are generated electrostatically from capacity changes produced by rotating wave-form electrodes. Harmonics are not produced separately but in groups, so that wide varieties of tone can be produced with a minimum of circuits. Valves are used only for straight amplification. Although the organ occupies a very small amount of floor space, it has a tonal quality which is remarkably close to that of a good pipe organ. Specially designed circuits provide delays (both before and after the depression of a key) which simulate the speaking characteristics of actual pipes with remarkable accuracy, and the instrument has none of the characteristics usually associated with electronic musical instruments.

Ferranti, Ltd. (Edinburgh), displayed a slow-speed relay computer designed to demonstrate the technique of automatic solution of problems in logic. Complex logical problems can, when broken down into a number of 'rules' or logical restrictions, be solved in a very short time even by this slow-speed machine. Two models were demonstrated. One obtained the solution by trying all possible combinations of the variables in turn; this model would give all the possible solutions to a given problem. The other does not try all combinations but is made to converge on a correct solution; this form is much more rapid, can deal with a greater number of variables but gives only one of the possible answers.

Also among the 'guest' exhibits was an amateur radio station in full operation, complete with home-made radio transmitters and receivers and a television receiver.

In the research section, Imperial Chemical Industries (Dyestuffs Division), Ltd., displayed a light-flux integrator. A photo-cell charges a condenser which triggers a flip-flop circuit at a given charge-level. This operates a counter, discharges the condenser and resets the circuit for the next count. A range of instruments involving transformer-type electromagnetic displacement gauges were on show. One such device measured the rate of wetting of a textile sample in water by recording the movements of a torsion balance, to which the sample was attached, as the water was absorbed.

The Electrical Engineering Department of the Manchester College of Technology displayed apparatus illustrating both research carried out in the College, and devices used in teaching. In the former category was an apparatus for indicating the rate of change of mains-frequency directly on a single dial, and designed for use in power stations. A useful device for teaching purposes was a harmonic synthesizer in which one could see, directly on a cathode-ray tube screen, the effect of adding together various proportions of different harmonics.

In the trade section there was a bewildering variety of equipments, all beautifully finished and a large proportion of them actually in operation.

Ferranti, Ltd. (Hollinwood), demonstrated their mercury–argon crater lamps, which give a light output directly proportional to the current passing through the lamp. These have wide application in sound-film recording and picture transmission, as the light can be modulated at frequencies up to 12,000 c./s. Among other interesting items was a new flat-faced television picture-tube with a 14-in. diagonal rectangular screen.

Fielden (Electronics), Ltd., demonstrated a yarn-irregularity meter. The instrument effectively determines the mass of a centimetre length of yarn, instantaneously present in the gap of a special condenser head, in terms of its dielectric properties. The instrument then notes the irregularities, integrates them over a predetermined period and presents the result, on a single dial, as the average irregularity expressed as a percentage of the average mass of the sample. The reading is quite steady and independent of the speed at which the sample is passing through the instrument.

One of the most interesting exhibits on the stand of Marconi Instruments, Ltd., was an audiometer assembly, specially designed for measuring the hearing acuity of young children. The instrument incorporates a standard pure-tone audiometer. The portion of the instrument visible to the child is brightly decorated in nursery style and consists of a loud-speaker and a 'peep-show' arrangement. This is so devised that a brightly coloured picture becomes visible when the child presses a button, provided that a test signal is being applied to the loud-speaker.

The Metropolitan-Vickers Electrical Co., Ltd., displayed their high-speed, recurrent-wave-form monitor which gives, on a cathode-ray tube screen, a trace of a recurrent wave-form with frequency components up to 300 Mc./s. In any one cycle, the instantaneous amplitude at some one point of the wave-form is measured. On successive recurrences, the instantaneous value at other points is recorded and after about 200 cycles a complete picture of the wave is available.

Mullard, Ltd., had on view a number of important additions to their range of valves, including a new disk-seal ultra-high-frequency triode, with a new type of cathode which permits closer spacing of electrodes —with consequent higher maximum frequency of operation—than has hitherto been obtainable, a series of sub-miniature valves and the first members of their range of image-converter tubes.

The Exhibition Committee deserves special congratulations on the organization, which, at any rate to an outside observer, appeared to be particularly free from technical hitches. C. A. TAYLOR

RESEARCH AND DEVELOPMENT IN THE SIMON ENGINEERING GROUP

By DR. W. RHEINALLT THOMAS

Director of Research

THE year 1908 saw the establishment of the first Simon Laboratory for examining and testing the materials used and produced in the coke ovens and coal-washing plant then being built by the firm. In 1912 tests associated with the manufacture of sulphuric acid were also undertaken. In the period between the two World Wars, the Laboratory was enlarged on three occasions to cater for advances in the design of existing plant and the introduction of new activities, which now include the production of power stations, turbine gears and a wide variety of chemical plant and mechanical and pneumatic handling machinery. Each department had also set up its own small teams of research workers and technical development engineers.

Tremendous expansion followed the Second World War, as demonstrated by the fact that orders to the value of £75 million have been taken at home and abroad, and it became clear that existing arrangements for testing, research and development were inadequate. Plans were drawn up to meet the situation, and building began in mid-1949.

On July 3 last, Sir Henry Tizard opened the new buildings, consisting of a central research block, a testing wing housing what was known as the Laboratory and now forming part of the Research Department, and the first of two development wings. These new buildings are almost entirely devoted to the research and development interests of Simon-Carves, Ltd. The Henry Simon companies forming the other half of the Simon Engineering Group, and with very different fields of activity, have entirely independent facilities for research and development, although there is the closest co-operation, particularly where problems of mutual interest are concerned.

The central research building, 159 ft. long, 45 ft. wide and 45 ft. high, contains four research laboratories, microscope, balance and dark rooms, as well as sections for testing metals and refractory and building materials. The library, information room and offices occupy the central portion of the first floor.

The testing wing on two floors is 105 ft. long, 55 ft. wide and 25 ft. high, and is specially designed to cater, on a much enlarged scale, for the activities of the old laboratory. The chemical work is carried out on the first floor, where four laboratories and ancillary rooms are provided. The ground floor contains six laboratories for the mechanical and physical testing of coal and coke, as well as a large workshop capable of dealing with all research and development requirements.

The development wing is a single-story building 165 ft. long, 55 ft. wide and 45 ft. high, and is devoted to experimental pilot plant on coal washing, coke ovens and pneumatic handling machinery. Until such time as the second wing is erected, space has been allocated in the existing wing to the chemical and power-plant development sections.

The main lines of activity fall into four broad classes: chemical analysis and materials testing; research; information; technical development. The division is arbitrary but convenient; overlapping is inevitable and only brief descriptions are given here of a few features of the work.

Before any plant is designed, exhaustive laboratory investigations are carried out on the materials to be used and produced, so as to provide the designer with data that will enable him to predict accurately the suitability of the raw materials and guarantee the performance of the plant.

For coal-washing plant design, information is given on the separation of coal and shale and of the fine coal and tailings as well as for the treatment of water for re-circulation. The assessment of coal for use in coke ovens involves proximate and ultimate analyses, determinations of the swelling properties, the yields of coke and by-products and analysis of the gases evolved. For boilers and power plant using either stoker or pulverized fuel, the calorific and ash fusion values are also determined.

The refractory materials employed in coke ovens are subjected to stringent tests for completeness of firing and strength under load at high temperatures and for resistance to abrasion and to sudden changes of temperature. Building materials undergo rigorous tests and analyses prior to use. A number of mechanical, physical and chemical tests are also carried out on the metals used in plant construction.

The general chemical analyses cover a wide range of organic and inorganic compounds as well as complex ores. Forty-four by-products of coal are analysed as a matter of routine. In connexion with the manufacture of sulphuric acid, catalysts, pyrites and the finished acid are examined, and such problems as treatment of waste acids and gases and phenol recovery from effluents form part of the programme.

To meet the needs for testing facilities on sites, a self-contained mobile laboratory has been fitted up and, by means of interchangeable cabinets, equipment can be quickly changed to permit tests on every type of plant built.

Research on a centralized as opposed to a departmental basis is of recent origin. Some of the problems embrace the activities of the organization as a whole; others are mainly of sectional interest. Reference is made to one of each type.

One field of common practical interest concerns small particles which are involved in the collection, extraction and disposal of industrial mists and dusts; the combustion of pulverized fuel and sulphur-bearing ores; sedimentation and studies in magnetization for dense medium washing.

The restriction of imports of raw sulphur for sulphuric acid manufacture has made it urgently necessary to devise means of purification and recovery of sulphur from alternative sources. The fields of investigation cover the filtration of molten sulphur, the flash roasting of iron pyrites, recovery from waste gases and spent liquors, and removal of hydrogen sulphide from town's gas.

The information section comprises a library and an information staff dealing mainly at present with the scientific and technical needs of the organization. By virtue of its activities it will possess an over-all generalized picture of the whole field of interest rather than a specialized knowledge of part of it.

The three main contracting departments in the organization are the coke-oven and coal-washing department and the power and chemical plant departments, and each has its own technical development sections. Work, hitherto, has been largely carried out on full-scale industrial plant. With the advent of the new wing, however, experiments on the pilot-plant stage will be carried out at first for rationalizing the design of existing plant and later in applying fundamental data to the design of new plant.

The new wing houses a complete dense medium coal-washing plant to one-third full scale, in which up to 25 tons of coal per hour can be treated, and effective separation of coal and shale differing only slightly in density is achieved. From trials on this plant and from the results of the associated laboratory tests, it is possible to erect full-scale plant of guaranteed performance. It will also be used for improving performance and for trying out new ideas. A small-scale self-contained coke oven has also been installed, and the results obtained can be translated to full-scale practice. An integrating radiometer establishes the combustion characteristics of domestic coke.

A pilot distillation plant in process of erection represents development of a new process where an entirely new design of fractionating column promises high efficiency in small volume.

The development sections of the power plant and chemical plant departments await the erection of the second development wing. In the meantime their work continues to be done largely on actual plant; but they have been allocated space temporarily in the existing wing. A test assembly of axial cyclones for gas cleaning has been erected, and at a later stage pilot plant for work on electrostatic precipitation will be installed. The chemical plant section is also co-operating with the British Iron and Steel Research Association in developing a method of recovering sulphuric acid from spent pickle liquor at steelworks. Among the main problems which the power-plant development section proposes to examine in detail are the behaviour and characteristics of pulverized fuel, the treatment of carry-over in steam and the expanding of tubes into drums and headers.

Recruitment of staff for the research department is proceeding and the ultimate establishment proposed will total 55, consisting of the director of research, twelve graduates of varying degrees of seniority, twenty-seven laboratory assistants, ten junior assistants and an administrative staff of five.

Each technical development section has its own staff headed by a senior scientific man. The coke oven and washer department has a team of six graduates, two senior and two junior assistants as well as a team for plant supervision and maintenance. The power-plant section has four graduates and one senior assistant, and the chemical plant section two graduates. Increases will be made when the second development wing is erected.

FACTORS CONCERNED IN FERTILITY OF MAMMALS

THE Society for the Study of Fertility held its second annual Conference on Fertility at Girton College, Cambridge, on June 20 and 21. There were four scientific sessions. The effects of experimental lesions of the hypothalamus in female rats on their œstrous cycles and mating behaviour have been studied by Miss H. M. Bruce and Dr. G. C. Kennedy (National Institute for Medical Research). No specific effects from such experimental lesions were seen on the cycles, whether the operation was followed by the development of obesity or not. However, in those rats which became obese, regardless of whether or no normal cycles continued, mating and pregnancy never occurred. Of ten animals in which obesity did not follow operation, only two mated. All the controls mated. Hypothalamic lesions produced in lactating rats did not always interfere with the continuation of lactation, even though obesity might supervene. The small, discrete, hypothalamic lesions did not result in gonadal atrophy in the rat. So far, only one sex effect could be localized in the hypothalamus, namely, a centre controlling the secretion of luteinizing hormone by the pituitary.

Mr. H. J. Cembrowicz (Ilminster) discussed the fertility-levels of bulls at an artificial insemination centre. Using as an index of conception the non-occurrence of œstrus in the three months following an insemination, it was found that there had been a rise in the conception-rate from 51 to 69 per cent between 1944 and 1950. During the same period, there had been a nearly five-fold increase in the number of inseminations per year, a six-fold increase in the number of inseminations per bull, and a seven-fold increase in the dilution of the semen used for insemination. Although semen production shows differences between breeds, with improved technique these become much less. Unlike the experience of the Milk Marketing Board, at his centre there has been no fall in conception-rate with increasing age of the bull, even when this reached eight and nine years. In the evaluation of the semen, motility has been found to be the best criterion. With different bulls, from one to three ejaculations per week can be obtained. It was found that 0·5 c.c. of diluted semen is just as effective a dose for insemination as 2 c.c.

Dr. Edmond J. Farris (Wistar Institute, Philadelphia) described his rat ovary hyperæmia test for the prediction of the day of ovulation in humans, and summarized some of the experimental work he has done to confirm its validity. He discussed its value, and the conclusions to be drawn from its use, in the practical handling of human infertility problems.

Dr. Nancy Laughton (University of Birmingham) described the bacteriological findings in cervical swabs taken from two groups of women, one showing positive and the other negative post-coital tests. (This work was done in conjunction with a study, reported by Miss Dorothy N. Shotton (of the Women's Hospital, Birmingham), on the cervical factor in human fertility.) The most striking feature was the absence of pathogenic organisms in all except one case from each of the two groups (this was *B. coli* in both instances). She had isolated from several patients of both groups a hitherto undescribed organism which is a small Gram-positive pleomorphic bacillus, 0·7 μ in diameter and 1–3 μ in length. It is culturally delicate and shows a rudimentary branching habit. From its morphology and cultural characteristics, which she detailed, it was concluded that it belongs to the order Actinomycetales. She gave it the provisional name *Corynebacterium cervicis*.

Experiments on the effect of thyroid hormone and of thiouracil on spermatogenesis in mice, rabbits and rams were described by Dr. M. Maqsood (Cambridge). Thiouracil interferes with the development of the germinal epithelium and decreases the number of interstitial cells. Thyro-protein, on the other hand, speeds up maturation of the testis, so long as the dose remains within the physiological range. In rams, thyroxin-treatment prevents the usual summer decline in spermatogenesis and improves the seminal quality generally. Thyroxin given to rabbits with previously poor records of semen production improves the seminal quality in all cases. Administration for forty-four weeks had no deleterious effect on the testes, whereas administration of thiouracil for a similar period led to complete testicular atrophy.

Dr. B. P. Wiesner and Prof. John Yudkin (King's College of Household and Domestic Science, London) described their experiments on the results of feeding a purified diet containing the known vitamin supplements to rats. They found that the interval from pairing to parturition is, in general, lengthened as compared with that of the controls fed on a stock diet; but most striking was the almost invariable death of the new-born young, in an emaciated condition, within two days of birth. Adding whole liver, and, to a lesser extent, vitamin B_{12}, corrected this effect, but only partially. It seems possible that the necessary nutritional factor (which they call 'R') may also be present in yeast. A method for the drying of liver at low temperature *in vacuo*, to produce a stable powder still containing factor R, was described.

Dr. T. Mann (Molteno Institute, Cambridge) described chemical methods of use in the analysis of semen. These include the estimation of fructose and citric acid and the demonstration of cytochrome by means of the microspectrometer. He also directed attention to the recent discovery in his laboratory of the presence of ergothioneine in seminal fluid. He was followed by Mrs. Clare Harvey (Exeter), who described the results of fructose and citric acid estimations in human semen. There are wide ranges of values for both these constituents, and no clear correlation with other seminal characteristics; though high fertility seems, in general, to be associated with relatively low fructose and high citric acid contents.

Dr. John MacLeod (Cornell University, New York) compared the seminal findings in 1,000 men of proved fertility with those in the husbands of 1,000 infertile marriages. His main conclusions are that sperm density, provided it exceeds 20 millions per ml., is of little significance; but high proportions of motile forms, with vigorous activity, is characteristic of the fertile males. There is no evident association of seminal abnormalities with repeated miscarriages.

Other papers were read by Dr. S. Bender (University of London) on the outcome of pregnancy in women previously sterile; Dr. Raymond G. Cross (Dublin) on tuberculous endometritis; Mr. Donald Young (Warrington) on surgery of the vas deferens; Dr. B. Sandler (Manchester) on the relationship of cervical hostility and asthenozoospermia in human sterility; and Dr. A. C. Crooke (Birmingham) on the effects of various adrenergic and cholinergic drugs on the gonadotrophin excretion of women with amenorrhœa.

INDIAN VETERINARY RESEARCH INSTITUTE

DIAMOND JUBILEE CELEBRATIONS

THE celebration of the diamond jubilee of the Indian Veterinary Research Institute, which was founded at Poona in 1889 and was transferred, in 1893, to Mukteswar, was held on March 11, 1951. Distinguished by the attendance of many workers from the different States of India, the gathering was addressed by the Hon. Shri K. M. Munshi, Minister for Food and Agriculture, who inaugurated, at the same gathering, the ninth meeting of the Animal Husbandry Wing of the Indian Board of Agriculture and Animal Husbandry.

India, said the Minister, possesses a quarter of the world's bovine population and also millions of sheep, goats, poultry and other animals; yet her production and consumption of milk are, perhaps, the lowest in the world. A sustained and multi-pronged effort to remedy this state of affairs is required and is being planned. Breeding, proper management and feeding of all kinds of livestock, and control of diseases from which they suffer, must be studied in a unified and comprehensive scheme which should be linked with India's "Grow More Food" campaign. The largest scheme ever presented by the Research Institute is, the Minister said, that for the eradication of rinderpest, which takes the heaviest toll of the lives of cattle and, in addition, debilitates and reduces the production of those beasts which survive. Everyone will endorse the Minister's hope that this scheme, to be carried out in collaboration with the Food and Agriculture Organization of the United Nations, will be financed and implemented soon. Meanwhile, a pilot scheme, designed to prepare the ground for the larger scheme, has been sanctioned by the Indian Council of Agricultural Research.

Discussing further the immense task of upgrading the millions of Indian cattle, the Minister commended the utilization, as part of the task, of artificial insemination. The central organization for the study of artificial insemination is housed in the Indian Veterinary Research Institute, and the Minister expressed the hope that this organization would be used to the fullest extent and that it would train the many personnel required for the Key-Village scheme.

The Key-Village scheme, on which the Minister asked the Animal Husbandry Wing to concentrate, has been drawn up by the Indian Council for Veterinary Research. It seeks to establish, all over India, a network of key-villages, the key-village being defined as a compact area consisting of one village or of a group of them, containing a total bovine population of five hundred. Each key-village will be surveyed to find out the distribution of cattle in it, its present productive capacity, the existing arrangements for the production and distribution of milk, the local supply of feeding stuffs and kindred matters. Bulls available in each area are to be examined and, if they are not satisfactory, they are to be castrated or removed and approved bulls are to be supplied. When the initial information has been obtained, the second phase of the scheme will introduce control of breeding, recording of milk production and other measures necessary for the improvement of the cattle. Still later it is hoped that the key-villages will operate as Government breeding farms helped by Government subsidies and supervision. Because there is an acute shortage of approved bulls in India, the possibilities of artificial insemination are already being studied, and the pilot scheme sponsored by the Indian Council of Veterinary Research is examining these possibilities in ten selected villages near Delhi.

Continuing a speech distinguished by its wide outlook and grasp of essentials, the Minister for Food and Agriculture expressed the view that the aim of breeding should be to produce a type of animal that can flourish under the conditions peculiar to its locality. The animal, he said, is fashioned by the type of husbandry used, by the kind of food and pasture available, by the factors in the environment which favour the occurrence of disease and by the climatic conditions generally. All these factors must be given due consideration. His speech concluded with a tribute to the Indian Veterinary Institute, the history of which, during sixty years of vigorous work, was outlined in an instructive address given to the gathering by the Institute's present director, Dr. S. Datta.

In a special jubilee issue of *Indian Farming*, which replaces the issue for March 1951, Dr. Datta describes the history of the Institute in greater detail. In this article, in fact, he gives a history of the development of veterinary science in India. Tracing its origin back to the men imported by the John Company in 1774 to look after stud farms, Dr. Datta describes the work of Moorcroft, Hallen and Cook and the appointment, in or about 1889, of the medical man, Dr. Lingard, as microscopist—and, soon after, bacteriologist—to the Government of India. To Lingard's work in the isolated surroundings of Mukteswar, Dr. Datta pays high tribute. The Indian Veterinary Research Institute should, he says, really be called the 'Lingard Institute of Animal Science'. He goes on to describe the work of Lingard's successors, paying just tributes to Holmes, Sir Leonard Rogers, Shilston, who unhappily fell a victim to glanders, Sir Percival Hartley, Macalister, Sheather, Pool, Doyle, J. T. Edwards, Cooper, Sir Frank Ware, Haddow, Macdonald and the last British director, Minett, who left the Institute, when the era of Indian independence began in 1947, to become animal husbandry commissioner to Pakistan.

For those who wish to know what 'Mukteswar' is now doing, there are, in this jubilee issue of *Indian Farming*, articles which describe the work going on in the Institute's various sections. The departments of pathology, bacteriology, parasitology, animal nutrition, biological products, poultry research and animal genetics are all confronted with varied and difficult problems. The section concerned with the training of workers is also an important one, because, as Dr. Datta points out, many senior workers have left Mukteswar to fill important posts elsewhere, and the need is great for experienced workers to carry out the extensive schemes that the Indian Government has in mind.

The future, it is clear, provides great opportunities for the Institute, and the solution of some of the difficult problems that confront it will provide fundamental knowledge that will be valuable to veterinarians all over the world. There is great and beneficent work to be done and a strong will to do it effectively. The good wishes of everyone interested in the welfare of man and his domesticated animals will go out to all those who are grappling with the complex problems that India now presents to her people.

Relative Abundances of Oxygen and Carbon Isotopes in Carbonate Rocks

The relative differences in the ratios oxygen-18 to oxygen-16 and carbon-13 to carbon-12 of some hundred and fifty carbonate rocks, including fourteen sedimentary limestones, ninety metamorphic limestones, twenty 'intrusive' carbonatites, twelve calcite crystals from Alpine clefts[1] and seven calcareous sinters have been measured. The aim of this investigation, which is being extended to include other carbonate rocks, is the accumulation of data that might lead to an interpretation of the isotopic differentiation in the carbonates on the basis of their geological history.

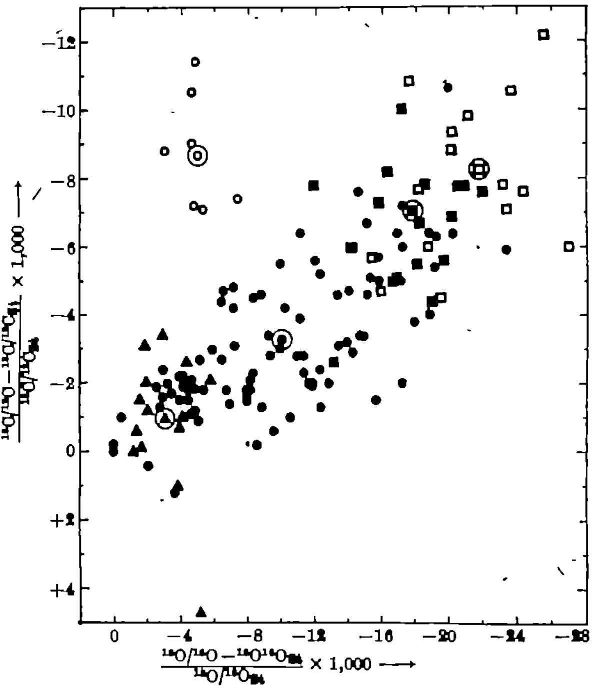
The determination of the relative abundances of the carbon and oxygen isotopes was carried out by means of a Consolidated–Nier double-collector mass spectrometer (type 21–201). The ratios oxygen-18 to oxygen-16 and carbon-13 to carbon-12 of each carbonate sample are reported relative to the corresponding quantities of an arbitrarily chosen standard limestone. The carbon dioxide samples necessary for this investigation were all prepared under the same conditions by decomposing the powdered rocks with 100 per cent phosphoric acid, according to a method developed by McCrea[2]. The results obtained in this manner are represented in the accompanying diagram. The deviations of the ratios oxygen-18 to oxygen-16 and carbon-13 to carbon-12 from those of the standard limestone (suffix St), given in parts per mille (°/₀₀), are used as x- and y-co-ordinates respectively. Negative figures thus indicate that there is less of the heavy isotope in the sample than in the standard. The carbon-13 to carbon-12 ratios are corrected for the variations in the oxygen-17 to oxygen-16 ratios, and the analyses were found to be consistent within about 1 per mille of the oxygen and carbon ratios.

The general character of the graph is at least partly explained by the fact that the isotopes of oxygen and carbon are fractionated in qualitatively the same way by most processes involving carbonate ions and carbon dioxide.

Considering the average isotopic composition of the different groups of carbonate rocks, it was found that the sedimentary limestones exhibit the highest abundances of the heavy isotopes. This can be understood from the low temperature of formation at which the oxygen-18 and carbon-13 in the carbonate are enriched by some 30 per mille and some 10 per mille respectively relative to the water containing carbon dioxide[3]. The scatter in the isotopic composition in this group may be attributed to local variations in temperature and isotopic composition of the water from which the carbonates were precipitated[3]. The calcareous sinters precipitated from fresh water are strikingly low in carbon-13. This is most probably due to the presence of dissolved carbon dioxide from decaying organic material. Such organic carbon is known to contain some 30 per mille less carbon-13 than the carbon dioxide in sea water[4].

On the other hand, since the isotopic fractionation between solid carbonate and its aqueous solution decreases with rising temperature of precipitation, we can see why the calcite crystals from Alpine clefts crystallized from hot solutions have the lowest abundances of heavy isotopes of all carbonates so far investigated. They contain, on the average, some 20 per mille less oxygen-18 than limestone precipitated from cold sea water. Since such limestone, as already mentioned, is enriched in oxygen-18 by some 30 per mille relative to sea water, one might conclude that the abundance of oxygen-18 in the solutions from rock pores from which the calcite crystals in the clefts were crystallized was some 10 per mille higher than that in sea water; always provided, however, that the temperature was 200° C. or more, conditions under which the fractionation of the oxygen isotopes becomes negligibly small. Similar conditions may be assumed to have prevailed in the formation of the 'intrusive' carbonatites which, according to the graph, are only slightly richer in heavy isotopes on the average than the calcite crystals from Alpine clefts. There is, in fact, strong evidence that the abundance of oxygen-18 in the water of rock pores increases with depth[5] and that magmatic water is some 10 per mille richer in oxygen-18 than sea water[6]. Though it is not possible as yet to account for the relatively large variations in the isotopic composition of the 'intrusive' carbonatites, it should be mentioned that these samples have a very similar oxygen-18 abundance to that of magmatic oxygen. It is reasonable to suppose that the corresponding ratio carbon-13 to carbon-12 is therefore significant for magmatic carbon.

The metamorphic limestones show a widespread variety in their isotopic compositions, ranging from those of the sedimentary limestones to those of the 'intrusive' carbonatites. No apparent relationships have yet been found between the isotopic composition



Relative abundances of oxygen and carbon isotopes in carbonate rocks.

▲, Sedimentary limestones; ●, metamorphic limestones (mainly from the Swiss Alps); ■, intrusive carbonatites (from Alno, Uganda, South Africa, Colorado); □, calcite crystals from Alpine clefts (all from the Simplon Tunnel); ○, calcareous sinters. Encircled points average isotopic composition of the different groups of the metamorphic carbonate rocks on one hand, and their physical and chemical properties or their age or geographical location on the other. It is most probable that the isotopic differentiation was caused by the different amounts of water and carbon dioxide passing through the carbonates at high temperatures during their metamorphic recrystallization. Limestones recrystallized with very small amounts of water had no opportunity of changing their original (sedimentary) isotopic composition, whereas carbonate rocks supplied with large quantities of ascending water and carbon dioxide finally attained the isotopic composition of the 'intrusive' carbonatites. In fact, such compositions were found only in crystalline limestones from contact zones with igneous or ultrametamorphic rocks where vast quantities of water and carbon dioxide were available. According to preliminary investigations, the abundance of the heavy isotopes generally decreases with increasing distance from the contact zones, and metamorphic carbonates having the isotopic composition of sedimentary limestones have been found mainly in the central regions of large limestone bodies. The distances over which a considerable change in isotopic composition may occur range from a few centimetres to several metres.

The results so far obtained suggest that the study of isotopic differentiation in metamorphic carbonate rocks might yield valuable information on the distribution and migration paths of the water and carbon dioxide during metamorphism.

Further investigations on the local distribution of the oxygen and carbon isotopes in well-known metamorphic areas are in progress and the results will be published elsewhere together with the details of this study.

I am indebted to Prof. A. Holmes (Edinburgh), Dr. E. Wenk and Dr. O. Grütter (Basel), for many helpful discussions and for furnishing the rock samples.

Preparation of Uniform Solid Samples for Radioactive Assay

The preparation of uniform solid samples of radionuclides is of paramount importance in radiochemical assay, using end-window Geiger–Müller counters, especially for radionuclides emitting low-energy beta-radiation. For comparative measurements (using identically mounted samples), it is essential that all the deposits should be uniform and of the same dimensions, so that the factors due to absorption and scattering in the sample are constant.

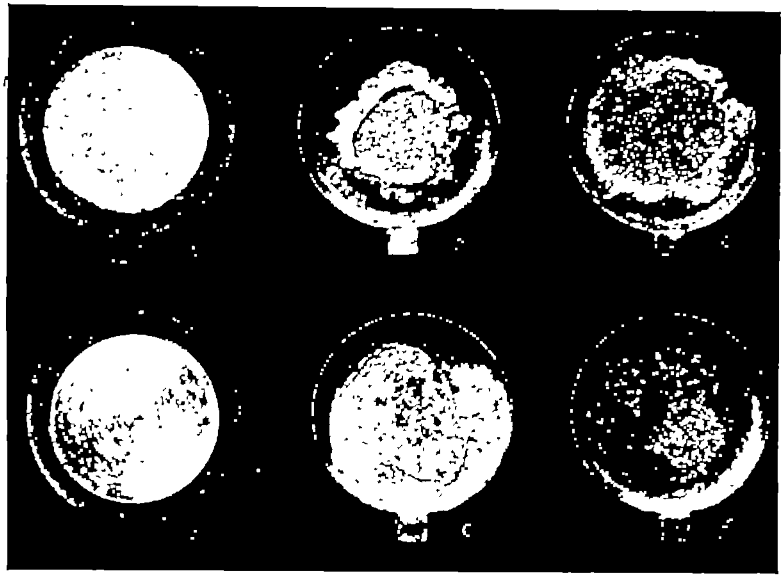
Many different methods for obtaining uniform deposits have been described[1] and these fall into two main categories: (1) those prepared by the evaporation of solutions; (2) those in which the deposition of a slurry of insoluble material is used.

The present method deals with the first case, that is, when the radionuclide compound is soluble. For routine work, a method often used is that of pipetting a small amount of the solution into a shallow metal dish and evaporating to dryness. Various devices have been used to induce uniform spreading and drying of the solution, as, for example, the addition of detergent or lens tissue or filter paper to the solution in the dish. It was found that methods involving the addition of a small amount of detergent did not give uniform deposits, and in some cases it caused the solution to creep over the edges of the dish. The present method, as well as giving a uniform deposit, accurately delineates the area of the active source, but requires no material to be added which would increase the absorption.

Circular stampings one inch in diameter with a protruding lug are made from 16-gauge aluminium sheet—the lug being used for ease of handling. The disk is held in a jig and the surface is 'turned-off' in the lathe from the centre outwards to a diameter of [illegible] in. to a depth of about 5×10^{-3} in., and a clean square-cut edge is left, care being taken not to touch the unturned part around the edge of the disk with the cutting tool. A known volume of the radionuclide solution is pipetted on to the centre of a disk and then rapidly evaporated beneath an infra-red heater in a current of hot air. The air stream is directed at the surface of the disk from all sides, through a series of holes drilled in a 5-in. diameter tubular brass ring. If the disk is placed at the centre of the ring, the air flow may be adjusted so that the liquid rotates. Thus, the solution is stirred until drying occurs, and the effects which usually cause uneven deposition are largely neutralized. When dry, the disks are fitted into a recessed metal plate which is then placed beneath the window of an end-window Geiger–Müller counter. (As the disks are flat, the active sample may be placed closer to the window than is possible with the usual type of shallow dish.)

The method has been tested using sodium bromide solutions containing either sodium-24 or bromine-82. When the deposit is of sufficient density to be observed, it appears as a matt finish of fine crystals uniformly distributed over the whole of the 'turned' surface. The present method is suitable for moderately heavy deposits; for example, it is found that the evaporated salt is confined to the 'turned' area even when 0·5 ml. of 1·0 *M* sodium bromide is used, whereas previously half this quantity evaporated in a shallow aluminium dish of similar size gave extremely non-uniform deposits. The best results are achieved when the disks are freshly turned.

A total of 10,000 counts was taken for each deposit and the results were corrected for decay; but corrections for resolving time were not made, as all the counting rates were of similar magnitude. Sources prepared with nominally equal volumes (checked by weight) from one active solution were used and all mounted in exactly the same manner, so that the geometry and the scattering effects of the mount and surroundings were constant. The effect of instrumental errors in counting was tested by counting one deposit ten times. The variation in counts was not significantly greater than that expected in a Poisson distribution; hence, instrumental errors could be considered to be negligible. The uniformity of deposition was tested by preparing ten disks of 0·2 ml. of 0·01 *M* sodium bromide containing sodium-24. The variation in counts was again not significantly greater than that expected in a Poisson



distribution ; that is, there was no experimental evidence of difference between the disks.

In the course of some other work, a large number of sodium bromide deposits containing either sodium-24 or bromine-82 have been tested using this method, taking three 0·2-ml. samples from each solution (from solutions of varying concentration up to 1·0 molar), and each set of three samples also gave results within the Poisson distribution.

Figs. *a* and *d* indicate clearly the uniform deposit obtained by this method, as compared with those obtained (*b*,*c*) by evaporating the solution in a dish, or those (*e*,*f*) when detergent is added to the solutions in the dish. In each case 0·2 ml. of sodium bromide has been used. Figs. *a*, *b* and *c* are for 1·0 *M* and Figs. *d*, *e* and *f* for 0·1 *M* solutions.

My thanks are due to Dr. A. Robson for discussion.

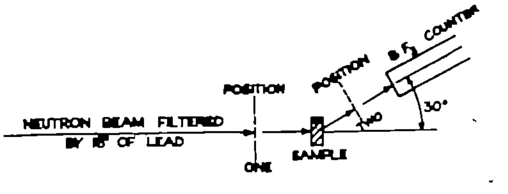
Inelastic Scattering of Cold Neutrons

The gain of energy of cold neutrons on being scattered by crystalline materials has been investigated with a beam of lead-filtered neutrons from the Harwell pile. The maximum energy of the neutrons in the beam was 0·0026 eV. and the mean energy was 0·0017 eV. The experimental arrangement is shown in the accompanying diagram. The counter and sample were carefully shielded from stray neutrons, and the sample was enclosed in a vacuum chamber to eliminate air scattering. The angle of scattering was 30 ± 5°. The transmission of a lithium fluoride plate (0·14 gm./cm.^{2}) was measured in positions 1 and 2 for different scattering samples. The transmission of the plate had been measured as a function of energy with a mechanical spectrometer, so that a mean energy of the beam could be determined from these measurements. From the measurement in position 1 the mean energy of the neutrons which are scattered into the counter is determined *before* they are scattered, and from the measurement in position 2 the mean energy is determined after scattering. The results are shown in the accompanying table.



The cross-section (assuming the scattering to be isotropic) was determined by calculating the ratio of scattering to total cross-section of the sample, from the ratio of the counting rates obtained with the sample and the thin hydrogenous sample.

Element	Thickness in mean free paths	1 Initial energy*	2 Final energy*	Cross-section if isotropic	Cross-section determined from transmission data
H	0·81	1·75±0·10	1·75±0·10	—	—
H	1·4	1·60±0·10	2·85±0·25	—	—
H	3·4	1·75±0·10	9·3 ±1·8	—	—
Be	0·60	1·3 ±0·3	5·0 ±1·7	?	—
V	0·92	1·7 ±0·2	1·5 ±0·2	6±1	4·7
Se	1·06	—	—	2·5±1	4±2
Mo	1·00	—	—	<0·3	<0·3
Fe	0·98	1·65±0·25	9·8 ±1·8	1·5±0·5	1·4

* The energy is expressed in units of 10^{-3} eV.

In the case of hydrogenous media, the presence of inelastic scattering is only observable with the thicker samples. In crystalline materials, the scattering cross-section at neutron wave-lengths greater than the Bragg limit is made up of inelastic scattering due to thermal vibrations and elastic incoherent scattering due to spin and isotope effects. The result with beryllium confirms that the inelastic cross-section is much greater than the incoherent cross-section, although the value for the final energy is too low because the inelastically scattered neutrons are appreciably Bragg-scattered. The vanadium measurements verify that the scattering is largely incoherent. The measurements with selenium and molybdenum were made to confirm the order of magnitude of the inelastic and incoherent cross-sections which had been determined from the total cross-section.

The scattering cross-section of iron[1] is known to be greater than the thermal inelastic cross-section at long wave-lengths, and the present measurements verify directly that the difference is due to inelastic scattering. It is believed that this is magneto-thermal scattering[2].

A New Method of Observing Compton and Other Incoherent X-Ray Scattering in Crystals

If a narrow cylindrical beam of copper K + white radiation is allowed to impinge on an iron foil of suitable thickness, placed in contact with a mosaic-type diamond (the foil being between the X-ray source and the diamond), an excellent divergent-beam pattern due to fluorescent iron K radiation can be obtained, superimposed on the Laue pattern of the diamond[1,2].

Even when the foil is removed, however, a weak divergent-beam pattern is still observed on sufficiently well-exposed Laue photographs, but it now corresponds to that expected for copper K wide-angle radiation. It was at first thought that this indicated the presence of copper as an impurity in the crystal, in sufficient quantity for a high proportion of fluorescent copper K radiation to be generated. This initial hypothesis was disproved by the following considerations and experiments.

(*a*) The effect is found for clear, colourless diamonds which would not be expected to contain copper as an impurity.

(*b*) Copper is a more unusual impurity than iron even in the opaque, coloured Belgian Congo diamonds which showed the copper K spontaneous pattern most clearly; yet, with an incident pencil of copper K radiation, for which the iron K fluorescence might be expected to be far more intense than any copper K fluorescence, no iron K spontaneous pattern was found.

(*c*) To check this reasoning, a spectrographic analysis of two Belgian Congo diamonds showing the effect was kindly undertaken by Miss Czapska, of Hilger and Watts, Ltd. This showed the presence of iron and silicon, but not of copper.

(*d*) A Laue photograph taken with cobalt K + white radiation showed a weak superimposed divergent-beam pattern due to cobalt K wide-angle radiation only.

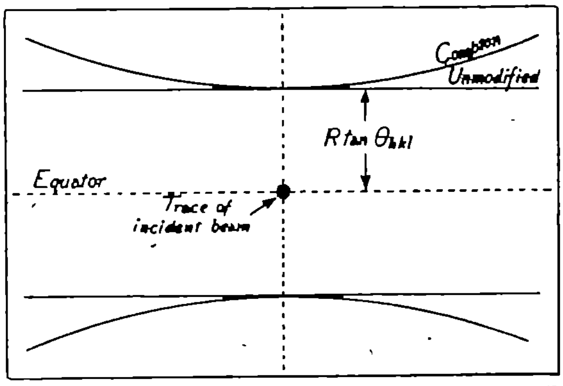
(*e*) Similar spontaneous wide-angle patterns were found for a mosaic benzophenone crystal using copper K and cobalt K incident beams respectively; and for a graphite crystal, using copper K radiation, when the incident beam was parallel to the basal plane.

Since the source of wide-angle radiation is within the crystal, and is not fluorescent radiation but of a kind similar to that in the incident beam, it must be either Compton scattering or imperfection scattering (including thermal scattering) or both.

This is confirmed by the observation that in the neighbourhood of the undeviated incident beam only reflexion conics, and no absorption conics, are recorded; which means, in effect, that the wide-angle source of radiation within the crystal has zero or low intensity near the incident beam direction, as would be expected for all such secondary radiation, but not for fluorescent radiation, or for low-angle scattering of any kind.

Owing to the difficulty of obtaining a pattern sufficiently intense for precise measurements of high-angle conics, it has not so far proved possible to distinguish between the effects due to the two types of incoherent scattering.

In principle, however, this could be done. In Compton scattering the wave-length of the scattered radiation is altered by up to 6 per cent, according to the incident radiation and the angle of scattering, whereas for imperfection scattering the wave-length change is only about 10^{-3} per cent. If the crystal is set with a plane (*hkl*) accurately perpendicular to the axis of a cylindrical camera, the divergent beam conics due to this plane will appear symmetrically on each side of the equator. If the pattern is due to the comparatively unmodified radiation, the conics will be a pair of lines parallel to the equator of the film; if it is due to Compton scattering the lines will diverge (appreciably for high-angle conics) as the angle of deviation from the incident beam increases (see diagram). Deviations from parallelism due to unwanted curvature of the film, etc., could be corrected for automatically by superimposing on the pattern a rotation photograph taken in the same orientation. In certain circumstances the nth-order conic will coincide with the nth rotation layer line, and any high-angle deviation could be observed. (For example, the deviation would be of the order of 2 mm. in the separation of the 220 copper $K\alpha$ conics for an angle of scattering of 140° for diamond with [110] parallel to the camera axis, using a cylindrical film of diameter 6·0 cm.).



Appearance of the *hkl* conic on a cylindrical film of radius R, when the planes (*hkl*) are perpendicular to the axis of the film. The curvature of the Compton conic is greatly exaggerated

The method is one which, if difficulties of technique are overcome, may be expected to give information about the relative amounts of Compton and imperfection scattering in various directions.

I wish to express my thanks to Prof. Kathleen Lonsdale for interest and advice during the course of this work.

Intensity Variation in Sunspots

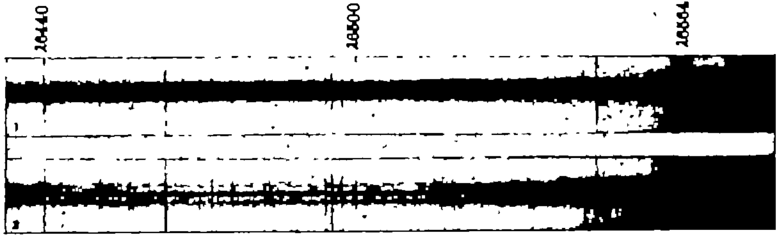
The most conspicuous and readily observed feature of a normal sunspot is a dark central umbra surrounded by a less dark penumbral fringe which, under good seeing conditions, appears to be composed of converging filaments directed radially inwards. Secchi[1] concluded from his visual observations that the penumbra is brighter at its inner edge, that is, towards the periphery of the umbra and darker at its outer edge. This feature is clearly shown in his drawings of sunspots.

Measurements of the variation of total energy across a sunspot with a thermocouple led Pettit and

Nicholson[2] to the conclusion that the total energy falls *continuously* from the photosphere throughout the penumbra to the umbra, where it remains fairly constant at about half the photospheric intensity. Wormell[3], who made similar measurements, arrived at the same result. He has remarked, however, that when allowance is made for scattered light, the observations can be accounted for by an umbra of constant intensity surrounded by a penumbra of constant higher intensity.

It is clear that these results do not support Secchi's observation that the penumbra is darkest at its outer edge and brightest towards the periphery of the umbra. Commenting on this, Pettit and Nicholson have remarked that "Secchi's observation is possibly an effect of contrast".

Recently, while taking spectrograms of the large sunspot of March 17–29, 1951, in the course of a study of the spectral intensity variation in sunspots, it was found that the umbral spectrum was bordered on either side by bright margins separating it from the penumbral spectra. The first observation of this was made on spectrograms taken in the H-alpha region of the first order of a 20-ft. grating spectrograph at 0430 hr. U.T. on March 24 (Fig. 1). The heliographic co-ordinates of the spot at that time were approximately latitude 12° N., longitude 15° W. The phenomenon was observed in a more striking manner on spectrograms taken at 0345 hr. U.T. on March 27 (Fig. 2). The heliographic co-ordinates of the spot at this time were latitude 12° N., longitude 55° W. Between March 24 and 27, the umbra of the spot had bifurcated and the bright bridge across the two halves of the umbra is clearly visible on the spectrogram of March 27.



Spectrograms of the sunspot of March 17–29, 1951. (1) March 24; (2) March 27

Visual examination of the photoheliogram of March 27 gives indications of a bright ring immediately surrounding the greater part of the umbra similar to that shown in Secchi's drawings. Examination of a number of old photoheliograms indicates that in the case of several spots the inner edge of the penumbra is brighter than its outer edge. A detailed microphotometric study of past photoheliograms taken at this Observatory is in hand.

Although several spot spectra have been taken on previous occasions, the phenomenon reproduced in the accompanying spectrograms has not been observed. The majority of the spectra do not show the sharp demarcation of intensity between the umbra, the penumbra and the photosphere which is so clearly visible on photoheliograms taken under good sky and seeing conditions, but show a continuous rise of intensity from the centre of the umbra through the penumbra towards the photosphere. This is presumably due to the wandering, owing to atmospheric unsteadiness, of the image on the slit of the spectrograph during the exposure. The two necessary conditions for accurate estimation of the intensity variation in sunspots are good sky and seeing and short exposure. A solar image of 60 mm. diameter formed by a 21-ft. photo-visual lens was employed in the present case and the exposures varied from 1 to 3 sec.

Effects of Ultrasonic Irradiation on the Coagulation of Cellulosic Solutions (Viscose)

The rate of coagulation of high polymeric colloidal solutions can be examined by a method devised by us, similar to that used for the study of the coagulation of recalcified blood plasma.

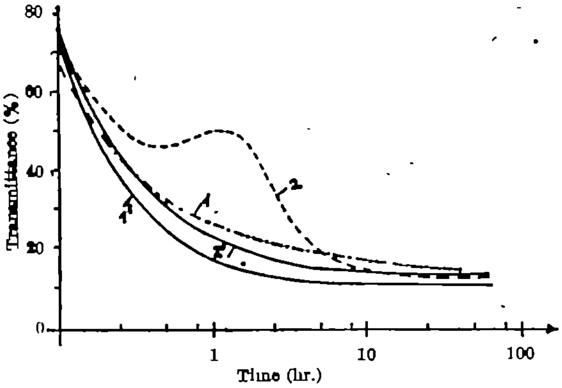
If the rates of coagulation and regeneration of a cellulosic gel are diminished by suitable means[1], it is possible to follow these phenomena spectrophotometrically. In this way a coagulation speed curve can be determined. The shape of this curve shows whether impurities are present or not, and also makes possible a study of the effect on coagulation of various chemical and physical agents (electromagnetic waves, ultra-violet radiations, etc.). We report here our first results concerning the effects of ultrasonic irradiation on the coagulation of cellulosic solutions and on the quality of the cellulosic lump obtained after regeneration.

Our method of slowing down the coagulation and regeneration rate consists in mixing drop by drop—contrary to industrial procedure—the diluted spinning-bath solution with the weakly diluted viscose (about 1 : 4) or cellulosic solution and stirring the mixture continuously in a regular manner. The process is stopped as soon as the coagulating reaction starts. In this way it is possible to initiate a low-speed coagulation and regeneration reaction which finally transforms the mixture into an optically homogeneous regenerated cellulosic lump, taking the shape of the vessel used. After achievement of this phase which lasts several hours, the lump begins to shrink and is transformed into a stiff and hard piece of cellulose; this transformation may last several days.

Three different types of ultrasonic apparatus were used. The first was an ultravibrator, frequency 800 kc./s., 50-watt total acoustic energy (maximum and 4·6 watt/cm.[2] maximal concentration, the second a Therasonel 015 (*ACEC*) with a frequency of 1,000 kc./s., 15-watt total acoustic energy, 1·8 watt/cm. maximal concentration, and the third a specially built experimental unit giving 50 watts total acoustic energy at a frequency of 3,200 kc./s. and an acoustic concentration of 5·5 watt/cm.[2].

The samples to be irradiated were placed in vessels of which the diameter was the same as the transmitting head. A cooling system using running cold water holds the sample at a constant temperature in spite of the heating effect of the ultrasonic radiation. Nevertheless, it was not possible to avoid specific thermal effects occurring in discrete points of a inhomogeneous medium which absorbs more or less energy than the surrounding liquid; microscopical temperature gradients are produced as during the treatment of inhomogeneous material with electromagnetic short-wave radiation[2]. Measurement of the ultrasonic dose (watt/cm.^{2}) is carried out by a differential thermocouple and that of the integral dose (watt. time) by insertion of small vials filled with an acidified solution of potassium iodide and starch[3]. Iodine is liberated by the action of ultrasonic radiation, and the depth of the blue colour—measured photometrically—gives the integral dose applied. In this manner the transmitted dose could be kept constant while using three different frequencies.

We have irradiated (*a*) the viscose before mixing with the coagulating solution and (*b*) the viscose after mixture with the coagulating solution. The three principal effects were: (1) outgassing by expulsion of included minute bubbles; (2) acceleration of the rate of coagulation and regeneration; (3) acceleration of dissolving and diffusing action of the spinning solution within the viscose.



Characteristic coagulation-speed behaviour of two different commercial viscoses (1 and 2). Curves 1′ and 2′ refer to the respective irradiated samples; their initial inclination (initial speed) is 2–3 times greater; however, the final transmittance is nearly the same in irradiated and non-irradiated samples. The abnormal behaviour (saddle form) of coagulation in sample 2 is not shown by the irradiated sample 2′

The cavitation effect occurring was positive and the speed of expelling hydrogen sulphide during the progress of regeneration was increased. The accompanying figure shows different photometric curves obtained under the influence of ultrasonic irradiation.

We have not found any remarkable differences due to change of frequency. Visible cavitation took place at about 0·65 watt/cm.^{2}. At that dose we had to irradiate for at least 15 min. to obtain a noticeable effect of acceleration on the rate of coagulation. The higher the dose the smaller was the time necessary to obtain an effect; however, there is not a linear relation between these factors. Macroscopic thermal effects do not seem to interfere with the process, because controls kept at 28° C., that is, 7° C. higher than the irradiated samples, showed no effect.

The acceleration of the dissolving and diffusing action of the spinning solution into the viscose and the outgassing of the mixture were clearly shown by the increase of light transmission through the sample at the beginning of coagulation when there is a nearly linear relation with the applied dose. The initial value of transmittance depends on the kind of viscose and coagulating solution, as well as on the quantities used.

As regards the structure of the regenerated lump of cellulose, we cannot be sure that the yield of the crystalline form and orientation are changed. However, the mechanical consistency of the lump is a little greater. Further work on this point is being carried out. The modification in the rate of the coagulation was only seen clearly when mixtures of viscose and spinning solution were irradiated.

I wish to thank the Director of Fabelta S.A., Brussels, for allowing me to publish parts of this work which were done in that laboratory.

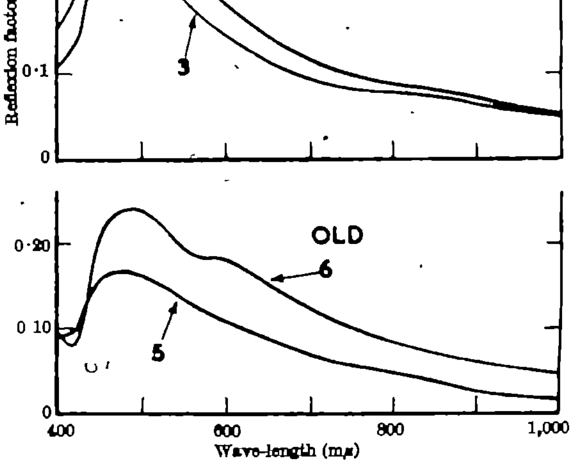
Spectral Reflexion Factor of the Cat's Tapetum

The physiological function of the tapetum in the eyes of animals of nocturnal habit is uncertain. However, it may fairly be assumed that by reflecting light incident on the retina back through the layer of end-organs, the tapetum reduces in some measure the absolute threshold for vision[1]. Since the tapetum is coloured, spectral sensitivities determined from absolute thresholds will also be modified. Murr[2], working on the light sense of the domestic cat, attributed differences in the wave-length of maximum visual sensitivity to differences in tapetum colour. In particular, he suggested that there occur changes of this kind during the life of the animal.



Reflexion factor of the tapetum from cats of different ages

To see whether tapetum reflexion was likely to be a factor in the current work of one of us (R. G.) on the cat's spectral luminosity curve, the spectral reflexion curves shown in the accompanying graphs were obtained. The tapeta of six freshly killed animals of different ages were dissected out, mounted in glycerine on 'black' glass, and measured on the G.E.C. recording spectrophotometer. Because of the rather small area of the tapetum—about 1·4 sq. cm.—it was necessary to use auxiliary lenses placed in the beam of the spectrophotometer in order to concentrate the light on the specimen. It was also necessary to apply a correction for light reflected not by the actual tapetum but by the surrounding black cardboard mask which exposed only the selected area of the specimen. The radiation specularly reflected at the glass–air surface of the cover glass falls on an absorbing surface in the instrument and is not included in the measured reflexion factor.

The corrected values given in the graphs show a main maximum reflexion factor at about 480 mμ and, in some cases, a rise as 400 mμ is approached and a rudimentary maximum at about 600 mμ. These last two features seem to occur together. It was obvious by direct inspection that the specimens were not uniform in colour. Probably at least two different pigments are playing a part. From the summary of the main features of the curves (Table 1), it appears that for the young cats the reflexion from the tapetum was weaker, and rather more to the blue than for the others, but the differences in this latter respect are not marked.

Table 1

Specimen No. and age of cat	Main maximum		Indications of secondary maxima	
	Wave-length	Reflexion at maximum	Below 400	Near 600
1 young	470	0·150	present	present
2 young	465	0·110	,,	,,
3 medium	470	0·254	absent	absent
4 medium	500	0·260	,,	,,
5 old	480	0·166	slight	,,
6 old	490	0·238	present	present

If the relative spectral sensitivity of the animal's eye would be V_λ if the tapetum were absent, some idea of the modification produced by the tapetum can be obtained by increasing V_λ by the factor $K(1 + \rho_\lambda)$. Here ρ_λ is the reflexion factor of the tapetum at λ and K is a constant introduced to restore the maximum sensitivity to the value unity. As an illustration, the changes in the photopic and scotopic spectral sensitivity curves of the human eye if a tapetum similar to specimen 1 or specimen 4 were introduced have been calculated in this way (Table 2). The changes are very slight.

Table 2

Photopic curve

λ (mμ)	460	480	500	520	540	560	580	600	620	640
V_λ	0·060	0·139	0·323	0·710	0·954	0·995	0·870	0·631	0·381	0·175
$V_\lambda(1+\rho_\lambda)K$ Tapetum 1	0·062	0·144	0·333	0·726	0·964	0·993	0·869	0·625	0·377	0·171
$V_\lambda(1+\rho_\lambda)K$ Tapetum 4	0·061	0·143	0·333	0·726	0·964	0·991	0·853	0·611	0·804	0·165

Scotopic curve

λ (mμ)	420	440	400	480	500	520	540	560	580	000
V_λ	0 097	0·313	0·570	0·796	0 962	0·933	0·597	0·318	0·124	0·036
$V_\lambda(1+\rho_\lambda)K$ Tapetum 1	0·093	0·309	0·577	0·807	0·970	0·933	0 589	0·310	0·120	0·035
$V_\lambda(1+\rho_\lambda)K$ Tapetum 4	0·088	0·301	0·564	0·798	0·968	0·933	0·589	0·309	0·119	0·034

It seems unlikely that the presence of a coloured tapetum can be modifying materially the observed spectral sensitivity curve of the cat's eye.

Estimation of Volatile Fatty Acids and Ammonia in Silage by means of Paper Chromatography

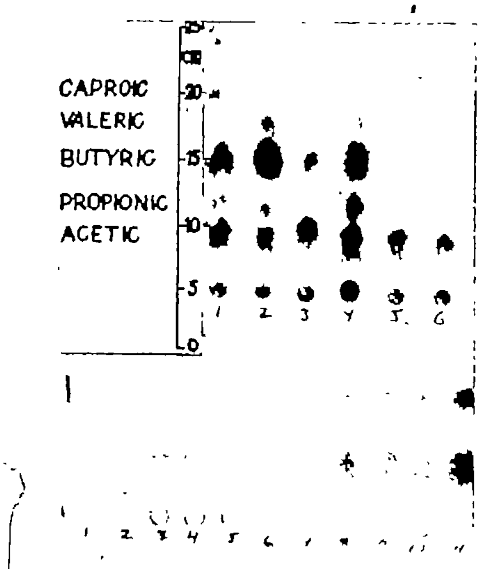
Silage-making is becoming more and more general in many countries, and it is necessary to pay more attention to its quality because the quality of milk and milk products suffers from a bad silage. The quality control of silage is therefore important. The simplest and quickest method of control is the determination of pH. In general, it can be said that when the pH of silage is between 3 and 4 (the AIV method) the decomposition processes (formation of carbon dioxide, ammonia and volatile acids) are slight in the silage and its quality is good. When the pH rises, the quality of the silage is lowered. Formation of butyric acid is then common, and ammonia is formed freely. Determination of these substances is of first importance in the control laboratories.

We have applied the chromatographic determination method of fatty acids developed by Hiscox and Berridge[1] to silage analysis, and have found that the analysis of butyric acid can be made directly from the effluent, which contains inorganic and organic ions. The spots have then frequently a slightly intenser colour than those produced by the corresponding amount of pure butyric acid in aqueous solution: this must be considered at estimation. Acetic acid cannot be determined in this way mainly owing to lactic acid, which proceeds almost at the same rate. If it is desired to determine acetic acid along with butyric acid, the acids must be distilled off from the effluent and the chromatographic determination made from the distillate.

The results of our determinations are illustrated by Fig. 1 and the accompanying table. Determination of butyric acid by paper chromatography is accurate enough for practical silage control.

Fig. 1 shows that silages of low quality may contain, in addition to butyric acid, also valeric acid (samples 2 and 4) and even caproic acid (sample 2). Propionic acid, too, often occurs.

Ammonia can be roughly determined by paper chromatography, also directly from the effluent (Fig. 2). Butanol–hydrochloric acid (2 vol. of n-butanol + 1 vol. of 6 N HCl) is used for the solvent, and the ammonia spot is developed by drawing the strip rapidly through



ig. 1. Paper chromatograms from six silage samples (raw fluents), with the following pH values (Nos. 1–6): 4·2, 4·3, ·0, 5·0, 3·8 (AIV), 3·9 (AIV) (upper paper) and from a control eries containing butyric acid 0·1, 0·2, . . . 1·1 per cent and acetic cid respectively 0·2, 0·4, . . . 2·2 per cent (lower paper). Solvent: -butanol saturated with water + ethylamine; paper. Whatman o. 1. Solvent frontier advanced in 18 hr. 28 cm. Acetic acid dvanced from the initial point 4–5 cm., butyric acid 10 cm.

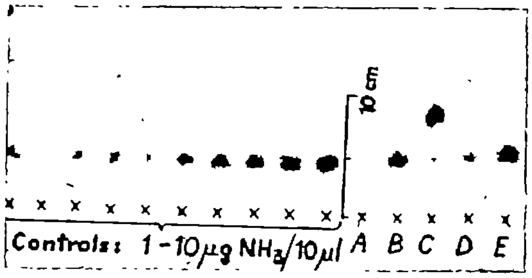


Fig. 2. Paper chromatogram from five silage samples (A–E) and from a control series with known amounts of ammonium sulphate

essler's reagent[2] and washing it in water. In ome silages a faster moving greenish spot is pro-uced by Nessler's reagent, in addition to an orange mmonia spot. This substance has not yet been dentified.

The optimum concentration region for ammonia n the paper chromatography is within 1 and 10 µgm., which means 0·1–1·0 mgm. NH_3/ml. when 10 µl. drops are used. The ammonia content of the effluents of good-quality silages is just within this region. Low-quality silages may contain considerably more ammonia and must be suitably diluted before the drop is placed on the paper. Since the salts contained in the effluent cause spreading of the spots, we have used about 1 per cent di-potassium phosphate in the reference solutions.

As the ammonia spot rapidly fades, the comparison of the spots must be made quickly, preferably when the paper is still in the wash-basin. Determination of ammonia by means of paper chromatography is not accurate (cf. the table); but it gives a rough idea of the ammonia content of silages. Distillation of an effluent made slightly alkaline to about half of its volume and titration of ammonia from the distillate gives, of course, a more exact result; but the paper chromatography may be useful in control laboratories as a work-saving method.

A detailed account will be published in *Ann. Acad. Sci. Fennicæ*.

A Phosphate Ester of a Tricarboxylic Acid in Liver

We have found that the compound isolated from dog's liver and previously considered to be a phospho-trihydroxyglutaric acid[1] is instead the phosphate ester of a tricarboxylic acid. The data indicate that the compound is 2-phospho-4-hydroxy-4-carboxy-adipic acid. Since work had to be interrupted for external reasons, a preliminary report is being made at this time.

The most important evidence was derived from oxidative degradation of the phosphate-free compound, which was obtained from the parent substance by prolonged acid hydrolysis or, in a more satisfactory manner, by action of alkaline phosphatase. Oxidation with permanganate or dichromate at 100° C. in the presence of mercuric sulphate and sulphuric acid (Denigès reagent) yielded the char-

acteristic precipitate of the mercury complex of acetone, which was further identified by distillation from the complex and by several characteristic reactions. Acid permanganate – bromine oxidation at 7° C. yielded 3·94 moles of carbon dioxide and pentabromacetone, which was identified by melting point, mixed melting point with an authentic preparation, and colour tests. The formation of pentabromacetone in nearly quantitative yield may be considered as a specific test for acetonedicarboxylic acid or for substances yielding it on oxidation[1-4]. Unlike compounds of the structure $R,R' = C = (COOH)_2$, which readily evolve carbon dioxide when heated in the dry state, the phosphate-free compound lost no carbon dioxide when heated up to 160° C. *in vacuo*. A stable, but hygroscopic, monolactone was formed easily, and there was some evidence of a second, weak, lactone linkage on the basis of titration in ice-cold solution. Analyses gave the following results:

	($C_7H_{10}O_8$) calc.	found
Equivalent weight of the phosphorus-free compound	74	71–78
" " " " " lactone	68	68
Molecular weight " " " " "	204	201

Elementary analysis of the barium salt of the phosphorus-free compound gave:

$C_7H_7O_8Ba_{1.5}$. Calculated, C, 19·8; H, 1·65; Ba, 48·5.
Found, C, 19·9; H, 1·54; Ba, 50·5.

With the phosphate ester, electrometric titrations gave 4·5–5·0 equivalents of hydrogen ion per mole of phosphate, and the equivalent weight was 66–69 (calculated for $C_7H_{11}O_{11}P$, 60·4). On oxidation with dilute permanganate solution, 2 moles of carbon dioxide were formed without hydrolysing the ester linkage. The oxidation product contained a carbonyl group, indicating the presence of a second hydroxyl group, other than that esterified with phosphate. It would appear that the carbonyl arose from the tertiary hydroxyl group by oxidative decarboxylation.

The following properties of the compound are of interest: (1) the phosphorus-free compound gives a dusty pinkish-red colour when heated with a mixture of pyridine and acetic anhydride (Fürth–Herrmann test[5]), similar to that of citric acid; (2) the phosphate ester shows only weak optical activity $[M]_{5461}^{23^\circ} = -3{\cdot}0^\circ$ (c, 0·26 M); (3) the phosphorus-free compound, when mixed with ammonium molybdate, was highly active $[M]_{5461}^{23^\circ} = +230^\circ$ (c, 0·003 M), a property shown by many hydroxypolycarboxylic acids; (4) acid periodate oxidation of the phosphorus-free compound for 10–60 min. gave 0·7 mole uptake of oxygen; (5) with hypoiodite, about six equivalents of iodine are consumed and iodoform is formed.

The possible biological role of the compound, which may be thought to arise from the condensation of phosphopyruvic and malic acids, appears of great interest.

We are indebted to Dr. G. Schmidt, Tufts Medical School, Boston, Mass., for a generous supply of intestinal alkaline phosphatase.

Dietary Origin of Urinary Methyl-Histidine

THE variable occurrence in normal human urine of a substance giving a green colour with ninhydrin on paper chromatograms (R_F 0·86 in phenol, 0·28 in collidine–lutidine) has been described[1]. This substance has been identified as methyl-histidine[2].

Previous to the identification of this amino-acid as methyl-histidine, we had observed that it was constantly present in large quantities in the urines of domestic cats kept in this Laboratory, while it was absent from the urines of laboratory rats. The cats were fed on a diet consisting of raw beef 73 per cent, boiled liver 24 per cent, bone meal 0·5 per cent, cod liver oil 2 per cent, and 'Marmite' 0·5 per cent, whereas the rats were fed on rat cake (Diet No. 41 of the Associated Flour Millers, Ltd.) which contains 8 per cent skimmed milk, 8 per cent fish meal and 2 per cent cod liver oil as the only constituents of animal origin. These facts suggested that the excretion in the urine of methyl-histidine might be associated with the meat diet. We therefore examined the urines of a number of species of carnivores, rodents and herbivores, with the results shown in Table 1. These observations are consistent with the hypothesis that the urinary excretion of methyl histidine is correlated with a meat diet.

Table 1

Our thanks are due to Dr. D. M. Walker for information about cows, and Mr. A. G. Searle about mice.

It might be reasonable to expect that the urinary methyl-histidine was derived from ingested anserine (beta-alanyl-methyl-histidine), which, as is well known, occurs in variable amounts in most vertebrate muscle. It should be noted that the urinary excretion of methyl-histidine is not correlated with the amounts of anserine present in the muscle of the species studied, as both the rabbit and the cat are known to contain relatively large and approximately similar concentrations of anserine in their muscles[3].

In order to explore the factor of ingested anserine, two human subjects were fed approximately 250 gm. roast rabbit meat, and their urine examined before

Table 2

each case 15 ml. of urine was applied to the paper in the right-hand corner. The individual ots were identified as: 1, glycine; 2, glutamine; 3, β-amino-isobutyric acid 4, anserine and methylhistidine

nd at different times after the meal. Rabbit muscle ontains between 200 and 500 mgm. anserine and 0–80 mgm. carnosine per 100 gm. wet weight[3]. s in our other experiments, the urine was run on 0 cm. squares of paper under conditions previously escribed[4]. Chromatograms were also prepared in ach case from the urines after hydrolysis with 5 *N* ydrochloric acid at 100° C. for 24 hr. The results were substantially the same for both subjects and he results for one of them are shown in Table 2 see also illustration).

We found that it was not possible to resolve nserine from methyl-histidine satisfactorily where me or other substance was present in relatively large concentrations. Consequently the increase in beta alanine after hydrolysis was taken as an index of the amount of anserine present in the urine. In no case was an increase in histidine noted after hydrolysis, which makes it reasonable to assume that most of the beta-alanine was derived from anserine and not from carnosine (beta-alanyl-histidine), which also moves to a position similar to anserine and methyl histidine on our chromatograms.

The results of this experiment support the view that a carnivorous diet can give rise to the urinary excretion of methyl-histidine. Furthermore, it indicates that the large variation of urinary concentrations of methyl-histidine encountered in human urines can be accounted for in part in terms of dietary variations. The findings also suggest that the peptide anserine may be absorbed intact from the gut and that during the first few hours after absorption it may be excreted unchanged in the urine.

After the heavy protein meal ingested in this experiment, there was relatively little increase in the urinary excretion of other amino-acids to be detected on the chromatograms compared with the anserine and methyl-histidine excretion. This suggests that the renal thresholds for these substances are relatively low. Some support for this view has also been obtained in the cat, where chromatograms of up to 500 micro litres of plasma (after ultra-filtration) have failed to reveal any appreciable quantity of methyl histidine, even though this substance was being excreted in relatively high concentrations in the urine.

These results raise the question of the site and mode of hydrolysis of anserine in the body. Enzymes which will hydrolyse anserine and carnosine have been described in liver, kidney, spleen, small intestine mucosa and intestinal juices of various animals. It is also interesting to note that Parshin found the carnosinase activity of the mucous membrane of the small intestine of man was lower than all but one of the animals examined[6]; his results also indicate that this enzyme is most active in carnivorous animals. Species differences of this sort may well play a part in our results in so far as they may explain the finding of methyl-histidine alone in the urine of carnivorous animals and a mixture of anserine and methyl-histidine in the urine of human subjects fed a high protein meal.

We are grateful to Dr. E. Hindle and the Zoological Society of London for specimens of urine from various animals.

Kidney Citrate Levels in Nucleotide Shock

During recent studies on carbohydrate metabolism in shock, we have examined the citrate-level in the kidney of the fasting rat by Buffa and Peters's modification[1] of the method of Pucher, Sherman and Vickery[2], during the shock state produced by the parenteral injection of nucleotides. A marked increase ($P = 0 \cdot 01$) in the citrate content of the kidney occurred 1 hr. after the intraperitoneal injection of a lethal dose of adenosinetriphosphate (250 mgm. magnesium adenosinetriphosphate per 100 gm. body-weight in the strain of rat used, at an environmental temperature of 18–22° C.; see table). This increase was not maintained, and 4 hr. after the injection the level had returned to normal. In its time relationships this effect resembles that seen in fluoroacetate poisoning; but in the latter condition the increase in the citrate content of the rat kidney is much greater[1,3].

The kidney was chosen for study because it shows the most striking changes in fluoroacetate poisoning[1]. However, this effect of adenosinetriphosphate was not

Effect of the intraperitoneal injection of 250 mgm. magnesium adenosinetriphosphate per 100 gm. body-weight on the citrate concentration in the kidney of normal and medullectomized (40 days post-operative) fasting rats compared with the level in control rats given an equivalent amount of D-ribose

	No. in group	Citrate concentration in kidney (μgm. per gm. wet weight) Mean	Standard deviation
Controls	16	36	16·5
Normal rats:			
1 hr. after adenosinetriphosphate	11	93	44·3
4 hr. after adenosinetriphosphate	6	54	31·8
Medullectomized rats:			
1 hr. after adenosinetriphosphate	6	32	6·2

confined to that organ, for an elevated citrate-level was also found in the diaphragm. These results suggest some interference with carbohydrate oxidation during the shock state.

Little can be said, at the present time, concerning the mechanism of the effect. The magnesium salt of adenosinetriphosphate was used in these experiments; but there was no accumulation of citrate after the injection of molecular equivalent amounts of magnesium chloride. Nucleotide shock is accompanied by the liberation of adrenaline[4,5], and attempts were made to reproduce the effectby the subcutaneous injection of adrenaline hydrochloride (0·1 mgm. per 100 gm. body-weight). This had no effect on the citrate concentration in the kidney, examined 1 hr. after the injection, although the blood-levels of lactate and pyruvate at this time were of the same order as those found at a similar time after the injection of adenosinetriphosphate[5]. Although the adenosinetriphosphate effect could not be reproduced by injection of adrenaline, adenosinetriphosphate did not cause any increase in the citrate-level in the kidney when given to rats deprived of their adrenal medullæ (see table). Since the carbohydrate stores of the body are not mobilized in adenosinetriphosphate shock in the medullectomized rat, it would seem that the block in metabolism is only evident when large amounts of carbohydrate are passing through the metabolic cycle.

We think that these results may help to elucidate the mechanism of adenosinetriphosphate shock and, perhaps, of other forms as well; although striking changes in the concentration of citrate in the kidney have not, as yet, been found in tourniquet shock in rats.

Our thanks are due to the Medical Research Council for defraying the expenses of this investigation.

Isolation of Octadecan-1 : 18-diol from Spanish Broom

An examination of the non-saponifiable fraction of the absolute from Spanish broom (*Spartium junceum* L.) by chromatography on alumina has led to the isolation of a fraction which is retained tenaciously by the adsorbent. The fraction was recovered by extraction of the alumina with hot ethanol. Purification readily gave octadecan-1 : 18-diol, melting point 99° (found: C, 75·5; H, 13·2; active H, 0·6; calc. for $C_{18}H_{38}O_2$: C, 75·5; H, 13·3; active H, 0·7 per cent). Octadecan-1 : 18-diol, melting point 99°, was synthesized by the reduction of diethyl octadecan-1 : 18-dioate with lithium aluminium hydride[1], and a comparison of the synthetic and natural diols and of the corresponding diacetates and *bis*dinitrobenzoates established their identity. Confirmation of the nature of the natural product was obtained by its oxidation with chromic acid, which gave octadecan-1 : 18-dioic acid.

A number of higher straight-chain aliphatic compounds in which the terminal carbon atoms carry functional groups have been isolated from natural sources. Several long-chain $\alpha\omega$-dicarboxylic acids have been obtained from Japan wax[2], and sabinic acid (12-hydroxylauric acid) and juniperic acid (16-hydroxypalmitic acid) have been isolated from conifer waxes[3]. The natural occurrence of long-chain aliphatic $\alpha\omega$-diols has not previously been reported.

Ultra-violet Absorption of Reduced Phosphomolybdate

Estimation of phosphate with molybdate in the presence of a reducing agent is a well-established colorimetric method. Using excess of phosphomolybdate, reducing substances can also be estimated. This method was used by Briggs[1] for hydroquinone and by Neuberger[2] for homogentisic acid.

We have sought a quantitative micro method for the estimation of homogentisic acid. With Neuberger's method, the blue colour given by the small amounts handled was too faint to permit accurate estimation. However, these solutions were found to have a much higher absorption in the ultra-violet region. This is illustrated in Fig. 1, showing the absorption curve (*a*) for a solution (4 ml.) containing the following: homogentisic acid (50 μgm.); potassium dihydrogen phosphate (0·3 ml. 1 per cent) and ammonium molybdate (0·3 ml. of 5 per cent in 5 *N* sulphuric acid). Measurements were carried out in 1-cm. quartz cells in a Unicam spectrophotometer, Model *S.P.*500, and solutions were allowed to stand for one hour before measurement. The curve shows a maximum at 355 mμ, and absorptions measured at this wave-length were proportional to the quantity of homogentisic acid, as shown in Fig. 2 (curve *a*).

This method has been used successfully for the estimation of 20–50 μgm. homogentisic acid in urines, after chromatography on paper and extraction of the separated homogentisic acid[3]. No doubt the method is applicable to other substances which will reduce phosphomolybdate, provided that the oxidation

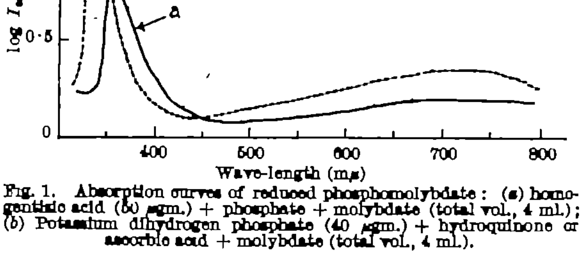

Fig. 1. Absorption curves of reduced phosphomolybdate: (*a*) homogentisic acid (50 μgm.) + phosphate + molybdate (total vol., 4 ml.); (*b*) Potassium dihydrogen phosphate (40 μgm.) + hydroquinone or ascorbic acid + molybdate (total vol., 4 ml.).

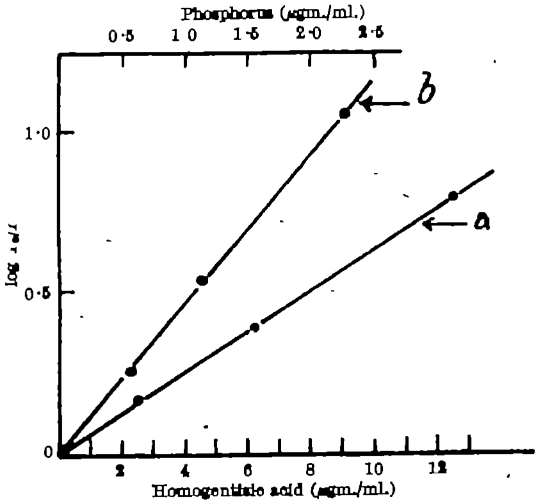

Fig. 2. Optical densities of various amounts of (a) homogentisic acid, measured at 355 mμ; (b) phosphate, measured at 335 mμ

products have negligible absorptions at 355 mμ. This is true for the oxidation product of homogentisic acid, *p*-benzoquinone-2-acetic acid[3]. Absorptions were also measured of a solution containing phosphate and excess of molybdate and a reducing agent. The latter was either hydroquinone or ascorbic acid; neither these nor their oxidation products have appreciable absorptions in the region of the observed maximum. Fig. 1 shows the curve (*b*) for a solution (4 ml.) containing potassium dihydrogen phosphate (40 μgm.), ammonium molybdate (0·3 ml. of 5 per cent in $5N$ sulphuric acid) and hydroquinone or ascorbic acid (0·3 ml. of 1 per cent in water). The curve was identical with either reducing agent. It will be seen that the absorption is again higher in the ultra-violet; but the maximum (335 mμ) is different from that of the homogentisic acid curve.

Measurements at this and lower wave-lengths necessitated rather large slit-widths for the control reagent solutions; but above 320 mμ, absorptions could be measured without decreasing the sensitivity. Absorptions at 335 mμ were proportional to the amount of phosphate (Fig. 2, curve *b*).

Application of the Dische Diphenylamine Reaction to Pyrimidine Deoxynucleosides

THE Dische diphenylamine reaction[1], which is specific for 2-deoxysugars[2], is not suitable for the estimation of pyrimidine deoxynucleosides[3,4] because of the incompleteness of colour development.

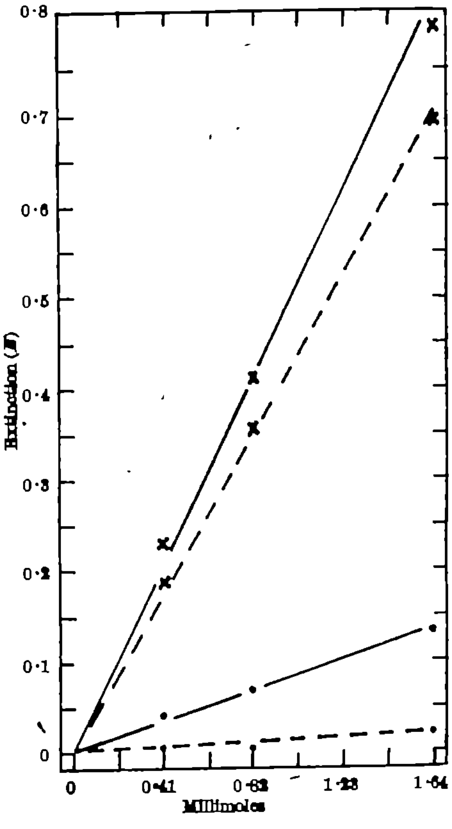
If, however, thymidine and deoxycytidine are given a preliminary treatment with bromine, there is a marked increase in colour development with thymidine, and a lesser increase with deoxycytidine.

As usually applied, the reactants in the diphenylamine test are heated in a water-bath for ten minutes or less. By extending the heating time to thirty minutes, there is no increase in colour intensity with either deoxyinosine or thymonucleic acid. As the colour development with brominated thymidine is more gradual than with purine deoxynucleosides, it is necessary, in the following experiments, to make comparisons after heating for thirty minutes.

Bromination is, with minor modifications, effected by the method of Massart and Hoste[5]. 2 ml. of the deoxynucleoside solution is heated with 0·01 ml. of bromine for five minutes in a boiling water-bath. Excess bromine is removed by aeration, and 4 ml. of the diphenylamine reagent is then immediately added.

The accompanying figure gives the extinctions at 600 mμ, obtained with equimolar solutions of brominated and untreated thymidine and deoxyinosine. Bromination causes a strong development of colour with thymidine, bringing it to a value approaching that of deoxyinosine. This is strong confirmatory evidence[6] for the assumption that there is a 2-deoxysugar residue in thymidine. Bromination of deoxyinosine under identical conditions leads to a complete suppression of colour development. This is consistent with the known lability of purine deoxyribosides in acid solutions.

A commercial sample of thymonucleic acid (from which the nucleosides used in this investigation were isolated) gives an extinction which shows that not only the purine deoxynucleosides, but also a portion of the pyrimidine deoxynucleosides fail to react with the diphenylamine reagent after treatment with



Effect of bromination on thymidine and deoxyinosine in diphenylamine reaction.

— — × — — ×, Brominated thymidine; —— ● —— ●, thymidine; — — ● — — ●, brominated deoxyinosine; —— × —— ×, deoxyinosine bromine. In contrast to this marked effect with diphenylamine, the total nucleoside concentration of such a sample of thymonucleic acid, when determined by the Mejbaum orcinol reaction[6], is only decreased by about 9 per cent. On the other hand, the free deoxynucleosides, with the exception of thymidine, do not develop any colour in the orcinol reaction after bromination.

It appears from these results that bromination causes a cleavage of the glycoside-N linkages of both purine and pyrimidine deoxynucleosides in thymonucleic acid. Further degradation of the deoxysugar is prevented by the phosphate attachments in position 3 or 5, which are not disrupted, as there is no release of organic phosphorus.

The fact that a proportion of the pyrimidine deoxynucleoside residues in thymonucleic acid fail to react with diphenylamine after bromination is evidence that the glycosidic attachment is less stable in these than in the isolated deoxynucleosides, and indicates that the C_1 of the deoxysugar of some of the pyrimidines in depolymerized thymonucleic acid are also engaged in "two distinct types of linkage (*a*) a form of polymeric linkage and (*b*) a glycofuranosidic attachment to the pyrimidine bases", as postulated for the deoxynucleosides of sperm deoxyribonucleic acid by Stacey and Overend[7].

Dutch-type White-spotting in Rabbits

THE Dutch rabbit usually featured in books on domestic rabbit keeping is a parti-coloured animal; the posterior half being coloured, while the anterior is largely white except for the ears and two eye circles of coloured fur. This pattern, however, is not stable. The characteristic pattern ranges from almost complete white (with blue eyes) to animals with odd white marks on the muzzle and fore-feet[1,2].

The extremely low grades of Dutch spotting are represented by small areas of white fur on the toes of the forefeet and point of the nose, the remainder of the body being normal. The expression varies from an unpigmented claw or small tuft of white hairs to a white stocking on either or both feet. White-spotting of this nature frequently occurs among rabbit stocks, and it is desirable to know the probable cause. I have been able to observe the incidence of such a case among a herd of rabbits kept for meat and fur.

A buck possessing an inch or so of white on the left forefoot was mated to five females devoid of white marks so far as could be seen macroscopically. 100 offspring were recorded as 59 self and 41 white spotted. The spotting varied somewhat, from a white toe to two inches of white foot, or a small white nose-tip to a thin streak extending up the forehead. The simplest explanation is that the male is heterozygous for a gene inducing the spotting, and the data do not conflict with the suggestion (χ_1^2 = 3·24, P = 0·1–0·05). Seven females from the se group were backcrossed to the buck, yielding 42 self 35 white-spotted. By the same hypothesis, χ_1^2 = 0·4608, P = 0·5–0·3. Three females of the F_1 white spotted class were also backcrossed to the mal yielding 11 self : 16 white-spotted as previously 6 more extensively marked. In the latter, the white spotting was expressed as almost all-white forefee and an inverted V on the forehead. Assuming th segregation of a single gene, χ_1^2 = 1·848, P = 0·5–0·3 Combining the F_1 and first backcross, we have total of 177, which were classified for sex as follows 45 self ♂♂ : 55 self ♀♀ : 35 white-spotted ♂♂ : 4 white-spotted ♀♀. An analysis of the segregation gave :

Item	χ^2	n	P
Genic	3·23	1	0·1–0·05
Sex	1·43	1	0·3–0·2
Linkage	0·02	1	0·9–0·8
	4·08	3	0·2–0·1

There is no evidence of partial sex-linkage.

The small deficiencies of white-marked animals may plausibly be attributed to weak expressibility or lac of penetrance of the white-spotting gene. No sig of heterochromia iridis was noted in any animal but this is scarcely surprising since the condition is not usually manifested except in high-grade Dutch It is possible that the gene described is comparable to Castle's du^d or Punnett's s or t.

Mygalomorph Spider in Samoa

MYGALOMORPH spiders are notoriously absent fro oceanic islands, owing to the fact that their youn do not habitually distribute themselves by sailing i the air on gossamer. It is interesting, therefore to record the occurrence in Samoa of *Idioctis helv* L. Koch, one of the Barychelidæ. This species wa recorded previously only from Fiji, and the Samoa specimens differ only in minor details from th descriptions of the Fijian ones. Mygalomorph spider of any kind are recorded in the south-west Pacifi only from New Zealand, Fiji, New Caledonia an the groups to the north. All these islands are situate in the relatively shallower part of the ocean. Mygalomorphs have not previously been recorded on th truly oceanic islands to the east.

Specimens of *Idioctis helva* were collected at tw widely separated localities on the island of Upolu in Western Samoa, and also on a minute uninhabite islet between Upolu and Savaii. From this distribution it seems unlikely that it was introduced at recent date. It inhabits a short, tough, silken tube provided with a trap-door, and all the specimens wer found within a few feet of high-water mark. Al were on rocks ; but if they also inhabit tree trunk they would be in a position to be transported acros the sea on floating timber or on canoes. Huma traffic between Fiji and Samoa cannot have a ver g history, so, if Fijian and Samoan specimens of *ootis* are really distinguishable, a longer separation the two populations and consequently natural onization would be indicated.

Two recent visits to Samoa devoted to collecting achnids have yielded a number of spiders belonging families not previously recorded in the Pacific, in ite of the fact that Samoa is one of the best-known alities so far as spiders are concerned. Members the Palpigradi and Schizomida were also obtained, d these orders do not appear to have been noticed fore in the area. Evidently considerable intensive ollecting must be done before much can be deduced om the geographical distribution of the more bscure invertebrate groups such as the arachnids.

Marsilea spp.: Materials for the Experimental Study of Morphogenesis

DURING recent years, improvements in the methods of sterile culture of organs and tissues have provided a valuable means of assessing the importance in morphogenesis of the various plant nutrients. It has been found that species of the heterosporous fern *Marsilea* grow well in sterile culture and show a sensitive response to changes in composition of the culture medium.

Sterile cultures are easily prepared from the resistant sporocarps, which, after treatment with absolute alcohol and bromine water, are washed once and opened in sterile water. Fertilization occurs overnight, and on the following day the young embryos may be transferred to tubes of the culture medium.

Much better growth is obtained in liquid culture than on agar media. The basic inorganic medium is a Knop's solution, supplemented by Berthelot's solution, as recommended by Gautheret[1]. The cultures are maintained at approximately 21° C., with a fairly low light intensity (100 foot-candles) which avoids any appearance of etiolation, but is inadequate for growth unless a suitable organic supply is present in the medium. Of the sugars investigated, sucrose supports the best growth, but adequate growth is also obtained with glucose or fructose. No other organic constituents are necessary, and in a medium containing sugar good growth continues even in complete darkness.

Fig. 1 illustrates a culture of *M. drummondii* A.Br. after five months of growth in a medium containing 5 per cent sucrose. Passing from the base towards the apex of the plant it will be noticed there is a gradual alteration in leaf form. The first acicular leaf (not shown) is followed by a spatulate leaf, then by bifid leaves, which in turn are succeeded by dorsiventral leaves, each with a quadrifid lamina, until finally the radially symmetrical 'four-leaf clover' type of the mature plant is obtained. Changes in the sugar concentration of the medium have a pronounced effect on this leaf succession and indeed on the entire morphology of the plant. Fuller details will be published elsewhere; but it may be indicated here that these effects are in part nutritional and in part osmotic. In this connexion, transfer experiments have yielded interesting results.

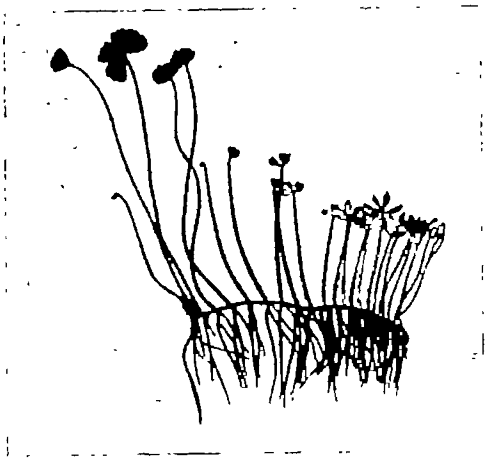

Fig. 1. *M. drummondii* after five months on medium containing 5 per cent sucrose. (Nat. size)

Isolated terminal growing points also grow well in the liquid medium: they afford excellent material for the investigation of the relation between nutrition and morphogenesis. Lateral growing points, one at the base of each leaf, begin active growth when the rhizome is divided up into separate nodes. The type of leaf produced by the laterals in part depends on the number of nodes from the base of the plant, and also on the previous nutritional history.

The sterile culture of pteridophytes is no new development[2]; but previous workers have not recorded the production of sporangia by their sporophytic plants. In the present work, which has been primarily concerned with the early stages of development, sporocarps were never obtained in cultures of *M. drummondii*. In *M. vestita* Hook and Grev., however, several plants produced sporocarps when cultured in a medium containing 5 per cent sucrose. The apical region of one of these plants is illustrated in Fig. 2. The sporocarps are quite normal in appearance; but since a dormant period is required, they have not yet been tested for viability. In Nature, strong light favours the formation of sporocarps, which are rarely produced on submerged plants[3,4]. It would seem from the present work that a high sugar concentration can take the place of the strong light normally required. Further work will be required

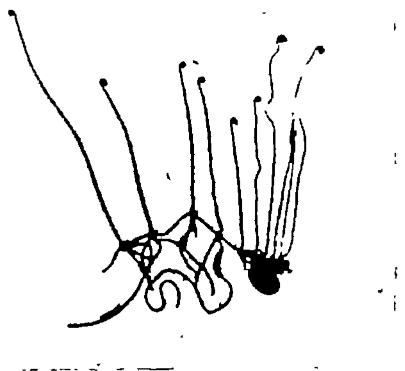

Fig. 2. *M. vestita*, after five months on medium containing 5 per cent sucrose. Apical region only. Some roots removed to reveal sporocarp. (Nat. size)

to establish this point; but it is significant that sporocarps were never produced on lower sugar concentrations.

I am indebted to Prof. Gilbert M. Smith, Stanford University, for the sporocarps of *M. vestita* and to Mr. Ernest Ashby for the two photographs.

Invalidation of the Genus *Vaughaniella*

AN examination of specimens of an alga at first assigned to *Vaughaniella rupicola* Boergs. has led to the conclusion that the genus *Vaughaniella* Boergs.[1] represents the basal rhizomatous portion of the genus *Padina* Adans. In southern Queensland, these flattened rhizomes, often showing transition to fan-shaped thalli, are found at the base of plants of *Padina commersonii* Bory in both estuarine and exposed localities; but around the margins of shallow lower littoral pools, on exposed rock platforms, rhizome development may sometimes take place without any production of fan thalli.

A more complete account will be published elsewhere.

An Insect Pest of Coconuts and its Relationship to Certain Ant Species

IN 1924 McDonald[1] and Welsford[2,3] reported the presence in Kenya, Tanganyika and Zanzibar of widespread damage of coconut fruits characterized by abortion of young female flowers, excessive dropping of young nuts and formation of necrotic lesions in those nuts which reached maturity. The damage was attributed to unfavourable soil conditions.

Present studies of the damage in Zanzibar have shown that it is caused by both nymphs and adults of a coreid bug which has been identified by the Commonwealth Institute of Entomology as a *Theraptus* sp. The feeding punctures of this insect are made through the calyx of the female flowers and into the young fruits, on which necrotic areas develop. Female flowers damaged in the bud stage, or when newly opened, are invariably destroyed; but if attack is delayed until after fertilization of the flower, the nuts may develop to maturity, the necrotic areas caused by the punctures developing into slit-like lesions in the husk. The damage appears similar to that caused by *Amblypelta cocophaga* China, in the Solomon Islands[4].

In the course of studies on the tree-nesting ant *Oecophylla longinoda* Latr. in connexion with clove diseases, it was noticed that damage by *Theraptus* sp. was absent or negligible in coconut palms occupied by this ant. The ant has been observed destroying *Theraptus* sp. nymphs on coconut palms, and it probably destroys or deters the adults. It is of interes that an *Oecophylla* species was apparently used as beneficial predator on citrus pests in China so fa back as the twelfth century[5]; and in the Far East Simmonds[6], Tothill[7] and Murray[8] have reported tha *O. smaragdina* is predatory on several coconut pests

Details of the yield of nuts from a single gatherin in a block of fifty-two coconut palms, of which sixteen were inhabited by *O. longinoda*, are shown i Table 1. The figures for yields shown in the tabl are approximately one-quarter of the annual yields

Table 1

	No. of nuts/tree	Percentage nuts showing lesions caused by *Theraptus* sp.	
		0–10 lesions/nut	More than 10 lesions/nut
O. longinoda present	21·2	16·5	6·2
O. longinoda absent	4·9	48·6	50·3

The figures show that, in the absence of *O. longinoda*, not only is the yield of nuts greatly reduced by *Theraptus* sp. attack, but also damage to the nut obtained is practically 100 per cent. Such damag results in reduction in size of nut and in yield o copra, as shown in Table 2.

Table 2

	Approximate No. of lesions/nut			
	None	0–10	10–20	>20
Wt. (lb.) of 100 unhusked nuts	286	264	229½	164
Wt. (lb.) of copra from above 100 nuts	47½	45½	36½	25½

Certain ground-nesting but tree-foraging ants, notably *Anoplolepis longipes* Jerd. and *Pheidol megacephala* F., ssp. *punctulata* Mayr., have replaced *O. longinoda* in many coconut areas of Zanzibar. The figures for coconut yields which have been obtained show that *Theraptus* sp. damage is not significantly reduced by the presence of the above two ant species. Observations on these ants in coconut palms show that they are not aggressive towards *Theraptus* sp.

Studies are in progress on the ecology of the various ant species with the object of determining conditions under which *O. longinoda* will replace the non-beneficial ants. Results of these and of studies of the problem on the coasts of Kenya and Tanganyika, as well as work on insecticidal control o *Theraptus* sp., will be reported later.

FORTHCOMING EVENT

Tuesday, August 21—Friday, August 24

ritish Institution of Radio Engineers (at King's College, bridge).—Radio Convention, Session 5: Television Engineering.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or fore the dates mentioned:

Demonstrator in Bacteriology—The Secretary, University llege Hospital Medical School, University Street, London, W.C.1 ugust 25).

Educational Psychologist—The Director of Education, 5 Port-bd Square, Carlisle (August 25).

Head of the Department of Engineering, South-East Essex chnical College and School of Art, Longbridge Road, Dagenham—he Chief Education Officer, County Offices, Chelmsford (August 25).

Mechanical and Electrical Engineers in the Works Department of the Air Ministry in connexion with the design, operation and aintenance of ground mechanical and electrical works services on .A.F. stations at home and overseas and on civil aviation stations—he Ministry of Labour and National Service, Technical and Scientific egister (K), York House, Kingsway, London, W.C.2, quoting .19/48A (Grade I) or D.370/50A (Grade II) (August 25).

Lecturer in Chemistry—The Principal, Wigan and District ining and Technical College, Wigan (August 27).

Assistant Lecturer (with a degree in zoology and botany) in iology—The Secretary, Royal Veterinary College and Hospital, oyal College Street, London, N.W.1 (August 31).

Chemist in the Insecticides and Fungicides Section at Long Ashton esearch Station, for work on the separation and characterization of he components of tar distillates—The Registrar and Secretary, The niversity, Bristol 8 (August 31).

Physical Chemist (Scientific Officer or Senior Scientific Officer rade) for work on boiler corrosion, with experience in high temperature orrosion (Ref. F.495/51A), a Physical Chemist (Scientific Officer or enior Scientific Officer grade) for work on soil corrosion, with experience and qualifications in electrochemistry (Ref. F.496/51A), Microbiologists (2, Scientific Officer grade) for work on sulphate-educing bacteria (Ref. G.255/51A), a Physical Chemist (Experimental Officer grade) for work on boiler corrosion, with experience in esearch on surface reactions (Ref. F.497/51A), a Microbiologist Experimental Officer grade) for curation of culture collection (Ref. .256/51A), and Microbiologists (3, Experimental Officer or Assistant xperimental Officer grade) for work on sulphate-reducing bacteria Ref. G.257/51A), at the Chemical Research Laboratory, Teddington—he Ministry of Labour and National Service, Technical and Scientific egister (K), York House, Kingsway, London, W.C.2, quoting the ppropriate Ref. No. (August 31).

Research Worker to take part in a programme of research in egeneration and tissue culture—The Secretary, University College, ower Street, London, W.C.1 (September 7).

Assistant Lecturer in Metallurgy in the Department of Coal as and Fuel Industries—The Registrar, The University, Leeds 2 September 10).

Engineers I at a Ministry of Supply establishment at Sevenoaks, ith experience appropriate to (a) development of optical instruents, including optical processing, and of drives for ultra high-speed ameras (Ref. C.461/51A), (b) development of radio communications nd monitoring equipment (Ref. D.343–4/51A)—The Ministry of abour and National Service, Technical and Scientific Register (K), ork House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 14).

Instrument and Radio Production Engineers in the Ministry f Supply in London, with extensive knowledge of airborne radio quipment, radio navigational aids, test and measuring equipment, ightweight and miniaturized electronic airborne equipment, quartz rystals, engine flight and navigational instruments, gyroscopic instruents, electric lamps—The Ministry of Labour and National Service, echnical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.338/51A (September 14).

Lecturer in the Department of Natural Philosophy—The ecretary, The University, Edinburgh (September 15).

Nuffield Research Fellowship in the Wheatstone Physics aboratory—Prof. J. T. Randall, F.R.S., King's College, Strand, ondon, W.C.2 (September 15).

Lecturer in Physiology (Cow and Gate Research Fellow)—The ean, Institute of Child Health, Hospital for Sick Children, Great rmond Street, London, W.C.1 (September 30).

Vice-Chancellor of the University of New Zealand—The ecretary, Association of Universities of the British Commonwealth, Gordon Square, London, W.C.1 (October 15).

Senior Lecturer or Lecturer in Botany at the University of Natal, Pietermaritzburg and Durban—The Secretary, Association of niversities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Assistant Chief Mechanical Engineer to assist the Chief echanical Engineer in the general administration of the Mechanical ngineering Section of the Public Works Department, Sudan—The udan Government Office, Wellington House, Buckingham Gate, ondon, S.W.1, endorsed 'Assistant C.M.E.4/123'.

Insecticide Chemist in the West African Cacao Research Institute—The Director of Recruitment, Colonial Office, Great Smith Street, ondon, S.W.1, quoting 27106/39.

Physicists to supervise and undertake research work involving he application of physical methods to the study of metals and the ontrol of new metallurgical processes—The Ministry of Supply, ivision of Atomic Energy (Production), Risley, Warrington, Lancs.

Plant Pathologist in the Agricultural Department, Tanganyika—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting 27059/277.

Production Chemists for Royal Ordnance Factories in Irvine, Bishopton, Chorley, Swynnerton, Glascoed, Pembrey, Bridgwater and in headquarters, London, to assist in technical control of administration of explosives and acids manufacture or ammunition filling, including development work—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.542/51A.

Professors (2) and Associate Professors (2) in the Faculty of Electrical Engineering at the Technion (Institute of Technology), Haifa, Israel—The Secretary, The Technion Society of Great Britain, 13 Mansfield Street, London, W.1.

Research Assistant (with appropriate honours degree or equivalent) to take part in studies mostly concerned with the use of chicks in nutritional research—The Secretary, National Institute for Research in Dairying, Shinfield, Berks., quoting Ref. 51/5.

Technical Engineer to undertake fundamental technical work in the application of engineering principles to the design of nuclear reactors and allied atomic energy projects, and to predict the performance of such plants—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

FREEDOM OF SPEECH AND THOUGHT

IN a recent lecture at the University of Manchester, Prof. W. Gellhorn, of the Columbia University School of Law, stated that there are now more physicists working on the atomic bomb project than existed in the United States a generation ago. The true significance of the position disclosed in his book "Security, Loyalty, and Science"[*] is only to be appreciated in the light of such a statement, at least so far as science is concerned. It is on the physicists, and especially on those concerned with nuclear physics, that the full impact of the security policies and the 'loyalty order' falls in the United States; and although Dr. Gellhorn addresses himself essentially to an American public, he has overseas readers in mind, and especially the effects of the situation on scientific advance generally. Other scientific workers, too, are obviously likely to be affected, especially by the loyalty order as at present administered; but in the main the security measures should chiefly affect physicists.

The book is one of a series of studies being made in the United States, under the general direction of Dr. R. E. Cushman of Cornell University, assisted by a grant from the Rockefeller Foundation, of the impact on civil liberties of the current measures taken by the United States Government to ensure internal security and to expose and control disloyal or subversive conduct. Much of the book is a factual summary of the way in which such measures are operated; but their effect on individuals and on scientific and national interests generally is assessed fairly on the assumption that national security may sometimes require restriction of some traditional liberties. Here Prof. Gellhorn's comments and conclusions have an interest that is not confined to the United States, and although there is little indeed in his book that has not already been expressed in discussions on freedom of science, security and loyalty in Great Britain during recent years, his argument may well prove as useful here as in the United States in a debate that is not yet concluded.

It is indeed a depressing reflexion that so much intellectual effort should be at this time diverted into the examination of such issues. This is not to doubt the justification for such an excellent statement of the real issues as Prof. Gellhorn has given us: indeed, if his argument achieves the revision of the loyalty programme and of the present personnel security procedures in the United States which he recommends, it should more than repay the time spent. There is no more striking feature in the book than the revelation of the appalling waste of administrative man-hours in such measures, with all the inquiries involved, to such little tangible purpose, even when we ignore what may be termed the secondary effects on recruitment and the quality of scientific work. As a demonstration of how not to seek security, this account of policy and practice in the United States deserves wide reading in Great Britain.

---

[*] "Security, Loyalty, and Science." By Prof. Walter Gellhorn Pp. ix+300. (Ithaca, N.Y.: Cornell University Press, London: Oxford University Press, 1950.) 24s. net.

To the British reader the book is valuable particularly for the balanced survey it gives of the factors that should be taken into account in determining security policy or measures, and for the clear warning it gives of the price which may be paid for a security which in the end is illusory. Prof. Gellhorn makes two points very clear. Security is relative rather than absolute, and it is to be achieved by positive and not by negative means. Scientific and technical excellence is the foundation of national strength and security in this field, and if the measures by which it is sought to prevent a potential enemy from learning of developments impede scientific and industrial advance unduly, the price may be too high. Weaknesses and insecurity rather than security may result.

Prof. Gellhorn directs attention to a third characteristic of security measures. The indirect effects which may be the most far-reaching in their consequences are rarely immediately apparent. The effect on the quality of recruits for the fields of work affected, whether in Government service, in industry or in the universities, is cumulative and long-term rather than immediate. It may be a decade before there is decisive evidence that the most original and creative minds are reluctant to undertake work in such fields where their initiative is restricted and freedom of publication is limited; still more so if not only they but also those related to them are subject to searching inquiries of the type which Prof. Gellhorn describes as conducted either in 'security clearance' or under the 'loyalty programme'. The evidence offered in this book is sufficient to justify uneasiness on this count; the effect of restraint on freedom of publication on the quality of research and the rate of scientific advance had received impressive demonstration before the Second World War.

On the present scale of atomic energy research, the possibility, not to say probability, of wasted effort is considerably enhanced, and Prof. Gellhorn rightly directs attention to the importance of this factor now that even in the United States it is realized that the available scientific and technical man-power is limited. Though the scale of research is less in Great Britain, it would appear from the debate on Lord Cherwell's motion in the House of Lords on July 5 that misgivings as to the effective use of such resources are already entertained. Lord Cherwell was concerned primarily with the present administration under the Ministry of Supply, and argued that this is unsuited to the type of development work required: Civil Service methods are not adapted to the flexibility and the rapid decisions and assumption of responsibility which are necessary. Moreover, rightly or wrongly, many of the best engineers and scientific workers are not attracted by Civil Service conditions, and the present arrangements give the security officers an almost impossible task. Nothing that Lord Alexander said in his reply really met Lord Cherwell's arguments, and the admittedly weak Treasury control destroys the only substantial reason for continuing the present arrangement and not transferring the whole project to some special organization of the public corporation type outside the Civil Service system.

Lord Cherwell's motion was carried against the Government, but Lord Alexander's remarks on the security question indicate that in spite of his doubts as to the appropriateness of a special or semi-Government corporation for handling the atomic energy project in Great Britain, there is little risk that the Government will be stampeded into fresh security measures comparable with those in the United States. Prof. Gellhorn, indeed, goes so far as to suggest that the cost of security has proved so high that the time is ripe for considering whether the loyalty order should be expunged.

Prof. Gellhorn's chapters on the balance sheet of secrecy, the proper limits of secrecy and the universities and security searches, form the core of his book; but there is one further and wider aspect of which account should be taken. This is discussed in a chapter on the need for fair procedures, and more briefly in his concluding chapter. The problem of security cannot be dismissed without account of the issue, not simply of individual freedom but also of justice. It is part of that wider issue of our time, and for this reason Gellhorn's book may be appropriately placed by the side of a collection of essays by Mr. Charles Morgan which has been published under the title of "Liberties of the Mind"*.

The common thread running through Mr. Morgan's several essays is the theme of liberty, the threat to liberty and the techniques by which the tradition of liberty is undermined. As Prof. Gellhorn shows in his book, even if national policies on secrecy in scientific matters are intelligently formulated—as, in fact, he believes they have been in the United States—they are liable to be applied inflexibly and unintelligently, unless regard is paid to the wider issues involving simple human justice. No element is so liable to be disregarded as a result of popular pressures, and such popular pressure commonly arises from misconceptions as to the nature of scientific knowledge or the real issues at stake. Prof. J. L. Stocks once observed of social philosophy that when men do not know the faith by which they live, they will be apt inadvertently to betray it, and the remark is equally true in this matter of freedom of thought and utterance.

With the exception of the introductory essay on "Mind Control" Mr. Morgan's essays have appeared before; but the gist of the book is contained in that essay and in the Zaharoff Lecture on "The Liberty of Thought" which follows it. In the first, Mr. Morgan develops the theme that liberty is now endangered in the mind itself. He analyses frankly the implications of the Soviet, the Mindszenty and other trials with their inexplicable 'confessions'. He suggests that a new technique is emerging which will enable any unscrupulous totalitarian government to 'possess', in the scriptural sense of the word, the minds of their subjects. Mr. Morgan does not suggest that this is an entirely new development. He sees it foreshadowed in the mid-Victorian era, and detects in Tennyson's

---

* "Liberties of the Mind." By Charles Morgan. Pp. viii+252. (London: Macmillan and Co., Ltd., 1950.) 12s. 6d. net.

'Sixty Years After'' a consciousness of what was happening. Nevertheless, although he notes the tendency of the mind to surrender more and more of ts liberties, Mr. Morgan seems inclined to attribute rather too much to overt attack, and attaches too ittle weight to the forces in contemporary life which, by weakening individuality and initiative and undermining the faith of the individual in the validity of his own mental processes, make him the easier prey of totalitarianism. We cannot continually, by precept and practice, contemn the virtues of individualism and extol the advantages of uniformity and conormity, and at the same time expect individuals to esist more effectively the attacks on their liberty, whether direct or indirect.

It has to be recognized that, in the welfare State, here is the danger that levelling down rather than evelling up standards may induce a uniformity and ack of enterprise which are fatal to creative work and the continuing advance of mankind. That danger was clearly recognized, for example, by Lord Beveridge, in his original report on social insurance as well as in the later one on "Voluntary Action". The preservation of the 'growing points', in science, art, technology, or indeed in government, is of vital mportance to a democracy, and both books direct attention to ways in which this is threatened.

In his essay on mind control, Mr. Morgan perhaps raises more fundamental issues, though he scarcely goes deep enough, and its value is rather as a chalenge or stimulus to thought than as an exposition of how to avoid the danger. Some of the issues he raises are of peculiar interest to the scientific worker: he makes clear, for example, how acute the question of the right use of science has become, and how mportant it is for men of science to address themselves to the questions of professional ethics, before their professional as well as individual influence is undermined. That in itself may involve questions of organization or the mechanics of government, which are discussed more fully by Mr. Morgan in his followng essay on the liberty of thought. Here, however, while fully as challenging, Mr. Morgan is inclined to overstate his case: he makes it plain that we can no onger take for granted much that we have been accustomed to accept from the days of Milton or earlier—we have now to be prepared to defend freedom at and from its source. But it does not follow that the dangers to democracy inherent in our present constitution are quite so serious as he suggests, or that the House of Commons is in the least likely to commit the excesses which are plainly within its power. He may underrate the restraining influence n Britain of the climate of opinion or the political tradition; but it is well that we should be reminded that the danger is there, that freedom is something to be safeguarded by our own efforts and determination. Liberty will perish, wrote Montesquieu, "when the legislature becomes more corrupt than the Executive", and we cannot watch without concern processes which weaken the sense of responsibility of either elected or elector.

In dealing with the mechanics of government, Mr. Morgan is, in fact, less convincing than Lord Justice Denning in his lectures "Freedom under the Law"; but none the less, the issues are made clear and some of his suggestions are parallel with those recommended by Prof. Gellhorn. He notes the questions involved in security against external attack, whether by armed forces or by enemy infiltrations which operate against the mind. He insists not only on the need for preventing intimidation of minorities, but also subversive intimidation by minorities. Liberty of thought, he suggests, has to be disengaged from the philosophical background of jurisprudence and made cognizable by positive law.

This challenge to intellectual leadership cannot be disregarded by scientific and other professional workers. The real danger to freedom of thought or utterance and all that Mr. Morgan understands by liberties of the mind lies really in just that indifference which enables the ill-disposed to seize institutions and prostitute them to evil purposes. Upon those liberties depend the functioning of every creative activity of mankind, in science, art and in every other field. Whether or not those dangers are exaggerated, the threat is real enough and Mr. Morgan sets it in the right context. Those who are concerned primarily with the advance of science must join forces with all who are concerned in safeguarding the liberties of men's minds and so strengthening the ramparts which defend such freedom. As Mr. Morgan writes: "There is no greater need than the world's need for a creative pause in which men shall have liberty to build and to preserve".

THE STORY OF ENGLISH FARMING

English Husbandry

From the Earliest Times to the Present Day. By Robert Trow-Smith. Pp. 239+16 plates. (London: Faber and Faber, Ltd., 1951.) 18s. net.

IN spite of its extraordinary interest, the history of English agriculture has attracted little attention from professed historians. The great classic "English Farming" by Lord Ernle first appeared in 1912: it was last re-issued in 1936 when Sir Daniel Hall added a chapter; but it is now out of print. A revision is under consideration of the Royal Agricultural Society and the publishers and will, it is hoped, soon be undertaken; meanwhile, the advanced student has no big general treatise to work on. Dr. and Mrs. Orwin's short history is admirable for the general reader and their larger works for the advanced student, especially for those interested in the land usage. So far no similar histories have been available dealing with the development of farming technique.

The author sets out to supply this. He starts right at the beginning with the advent of the first agricultural colonists, the Neolithic peoples who about 2400 B.C. came to Britain, bringing with them the seeds of wheat (incidentally, apparently some of its associated weeds also) as well as cattle and sheep, descendants of which can still be found in outlying parts of the country. Then comes a short account of the Romano-British period, of the agriculture of which, however, little is known, though it must have been fairly efficient to maintain a relatively large population of military and towns-people. A chapter follows on the Saxon period in which the author revels—rightly so, as they were true sons of the soil: the vast majority of the villages in the central and southern parts of England have Saxon names and were presumably founded by them, being cut out from the primeval forest, though how exactly this was done is not known. By the time of the Domesday survey, however, English agriculture was already highly developed.

From Norman times onward the picture is much more complete: Mr. Trow-Smith has cast his net widely and has an eye for picturesque detail. He points out that in the Middle Ages more of the grain produced in England was drunk than was eaten. He recalls the story of the thirty canons of St. Paul's who, in 1286, were said to have drunk two-thirds of the brew from 175 quarters of barley, 175 quarters of wheat and 720 quarters of oats—apparently averaging 1,500 gallons of ale apiece in the year—33 pints a day. One can only add, adapting one of Mr. Churchill's crisp phrases: "Some canon, some thirst".

Written accounts of English agriculture begin in the early part of the thirteenth century with Walter of Henley's "Husbandry", two anonymous treatises, and Bishop Grosseteste's "Rules" of about 1240. They were published in 1890 with a translation by Elizabeth Lamond and a description by Mr. Cunningham, and are liberally drawn upon by the author. Then followed the time of plagues and pestilences culminating in the Black Death of 1348, which greatly reduced the numbers of farm workers: recovery, however, seems in many places to have been rapid, suggesting that there had previously been a good deal of redundant labour in the villages, as often happens in peasant communities. The changes resulting from the subsequent decay of the manorial system and the long series of enclosures are well described, and the author then deals with the great developments of the seventeenth century.

During the Civil Wars some Royalist landowners went as refugees to Flanders, where they saw agricultural practices much in advance of anything they had known in Britain—in particular the culture of clover, sown grasses and other fodder crops that enabled livestock husbandry to be fully integrated with arable husbandry: this forms the basis of some of our best modern systems. The author gives numerous quotations from contemporary writers and a good selection of illustrations showing the implements they used. He emphasizes the fact that ley farming, new to some of this generation, was introduced in Britain in the seventeenth century.

The author rather condemns the high farming of the mid-nineteenth century because it relied for its success on oil cakes and meals got from overseas countries "at the expense of the fertility of foreign soils, and many parts of an eroded world are to-day paying the piper for the tune played at the call of the English mid-Victorian yeoman". This is scarcely fair. The overseas farmer had not taken up land at the behest of the mid-Victorian yeoman but in order to live: not wishing for a low-level subsistence farming, he produced for the market. He was free to dispose of his produce however he liked. Great Britain offered the best terms and he sent it here. The erosion set in not because he sold the grain—which he had to do in any event—but because he was using in semi-arid conditions cultivation methods developed for humid regions, and it was long before appropriate methods were worked out. The English farmer acted rightly in buying extra feeding stuffs while he had the chance—the Danish and Dutch farmers later on did the same to their great advantage; he is equally right in producing more of his feeding-stuffs at home now that he cannot buy from abroad.

A few errors have slipped into the text. The Rothamsted dates are wrong. The Broadbalk experiments were started in 1843, three years after the publication of Liebig's book, not ten years as the author states; Lawes's experiments on superphosphate had been started about 1838. Liebig did not demonstrate the effect of chemical nutrients on crop growth; he used the results obtained by others. One would like to have seen John Andrews, the farm labourer of Debenham, given the credit for discovering Chevallier barley: it was he that found it and grew it first; but the local parson, the Rev. John Chevallier, multiplied it for distribution so it was called after him. Apart from these minor defects the book is very interesting and well worth reading.

E. John Russell

CONTRIBUTIONS TO MATHEMATICAL STATISTICS

Contributions to Mathematical Statistics

By Prof. R. A. Fisher. (Wiley Publications in Statistics.) Pp. xvii+658. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 60s. net.

This book consists of reproductions of a selection of forty-two of the author's more important scientific papers, together with a biography by Prof. P. C. Mahalanobis originally published in *Sankhya*. However, it differs in many ways from the ordinary volumes of 'collected works'. The papers have been selected by the author, and each paper has been prefaced by a short note indicating the circumstances which gave rise to it, and its relation to the common knowledge, or common misapprehensions, current at the time it was written. The papers are reproduced photographically, to the original size, with manuscript corrections and amendments. This produces a pleasing variety of text, and ensures that no new printing errors are introduced. The corrections that have been made are also apparent, a point which is of importance if the results have been used as a basis for subsequent work. Further, this method of reproduction has the very great advantage that it has enabled the book to be produced at a much lower cost, and with far less proof reading, than would otherwise have been possible. In this connexion, indeed, the generosity of the editors of the various scientific journals in permitting reproduction of their papers—only one journal, *Metron*, refused permission to republish—is to be warmly commended.

The selection of papers has been well done, though it is inevitable that there will be some disagreement as to what constitutes the perfect choice. One might, for example, have wished to see included the paper on "The Influence of Rainfall on the Yield of Wheat at Rothamsted" (*Phil. Trans. Roy. Soc.*, B, 213, 89; 1924), which contains a very elegant and original method of estimating the effect of rainfall at different times of the year, if necessary in preference to the earlier and less important paper on the variation in wheat yield from the same field ("Studies in Crop Variation. I. An Examination of the Yield of Dressed Grain from Broadbalk", *J. Agric. Sci.*, 11, 107; 1920). As an example of historical research, the paper on Mendel's work ("Has Mendel's Work been Rediscovered?", *Ann. Science*, 1 (2), 115; 1936), which is almost inaccessible in the original, is of lasting interest, while the relatively trivial paper on the half-drill strip method by Barbacki and Fisher ("A Test of the Supposed Precision of Systematic Arrangements", *Ann. Eugen.*, 7, 189; 1936) seems scarcely worth reproduction without at least a reference to 'Student's' subsequent and not wholly unjustified criticism of it.

The collection will be of immense value to all mathematical statisticians, particularly those of the younger generation who have not had direct contact with the original articles when they appeared. As Fisher himself stresses in the preface, reference to original sources of mathematical research tends to be neglected—indeed, it is only by publications such as the present one that the ordinary student can hope to make any comprehensive study of the works of a single author. In the present instance, the study is of interest and importance, not only in revealing how the subject has developed, but also because many of the results obtained and methods described are still only available in the original papers.

The book is also a worthy monument to Fisher's achievement in mathematical statistics. Even to those who are closely acquainted with his work, it brings fresh realization of its immense scope and the genius that marks so much of it.

From the point of view of a student, there are, of course, defects in the use of collected papers by a single author in the study of a subject, in that only one side of a controversial issue is presented. In such a case what is really required is a collection of papers by different authors dealing with the same subject. The same is true when a subject is developed concurrently by several authors. Perhaps if the method of reproducing scientific papers adopted in the volume is found to be generally acceptable, collections of this kind dealing with specific subjects might be attempted.

POLLEN ANALYSIS

Text-Book of Modern Pollen Analysis

By Knut Fægri and Johs. Iversen. Pp. 168. (Copenhagen: Ejnar Munksgaard, 1950.) 16 Danish cr.

TO quote from the preface of this little work: "Pollen analysis is still a very young science . . . and [it] has developed swiftly during the last 10 years". The aim of the authors, two well-known Scandinavian workers, has been to set forth, fairly exhaustively but simply, the technique in all its aspects and applications. This has been done in seventeen (unnumbered) chapters, which cover the subject thoroughly, from a short historical introduction to the latest suggested aid in pollen-grain identification—a perforated card key. The over-all result is an excellent book that cannot fail to be of very great help to everyone, mature worker or beginner, concerned with the science.

Some points, cf course, in my opinion at any rate, invite criticism. In the chapter dealing with the pollen diagram, for example, it would have been more convenient for the reader if the example of a typical diagram (Pl. IX) had been inserted here instead of at the end of the book. As to the merits of different types of diagram, I have always held the opinion that the 'dissolved' (unhappy word) diagram as used by Dr. Godwin and his co-workers has much to recommend it for clarity and directness of appeal. It would have been helpful if an example of this type of diagram covering the (mainly peat) zones of the Post-Glacial Period had been inserted. The omission of any illustration of these zones is indeed strange, since pollen analysis, as we know it, after all was founded on peat; perhaps the answer to this riddle is to be found in the statement on p. 84 of the book, which reads: "For ordinary work one should never analyse peat if any sediment is available". This statement is altogether too sweeping. The 'ordinary' work of pollen analysis dealt, and still deals, with peat. Are we to understand, for example, that the fine work of Jessen on the Irish bogs, so recently published, is of little value? Surely not.

The pollen keys provided are 'artificial' keys, and result in many strange bed-fellows. They deal mainly with the pollen species likely to be found in deposits in north-west Europe. They will doubtless serve their purpose—but, as the authors are at pains to impress on their readers, a pollen herbarium is a *sine qua non* for the pollen analyst.

The book is pleasingly printed, and the authors acknowledge indebtedness to Miss Jean Allison and Mr. Philip Tallantire for linguistic advice and help in proof-reading. A number of awkward words and phrases have passed uncorrected, but these are not likely to mislead the serious reader. When a second edition is called for, however, as it well may be, the opportunity should be taken of correcting these solecisms—and making a good book better.

J. B. SIMPSON

AMERICAN DECIDUOUS FORESTS

Deciduous Forests of Eastern North America

By Prof. E. Lucy Braun. Pp. xiv+596. (Philadelphia and Toronto: The Blakiston Company, 1950.) 10 dollars.

THE deciduous forests of eastern North America are treated in this book predominantly from the descriptive point of view, and Prof. E. Lucy Braun adopts as a basis the view that those forests which to-day appear to have been little modified by man can be regarded as indicative of the climax communities of the original forest cover.

The deciduous communities dealt with are considered by the author to comprise nine major forest regions based upon physiognomy and similarity of floristic composition. Historic factors are recognized as playing an important part. Thus, the mixed mesophytic forest region of the unglaciated Appalachian plateau is not only particularly the home of the chestnut, *Aesculus octandra*, and the white basswood, *Tilia heterophylla*, but is also perhaps significantly the habitat of the tulip tree, of ancient lineage. This region is by far the richest in species, with a number of kinds of trees constituting the canopy, usually more than thirteen even in a small sample area, together with a rich herbaceous vegetation some of the characteristic members of which have contributed to the beauty of gardens in England (for example, *Trillium grandiflorum*, *Erythronium americanum*, *Phlox divaricata* and *Tiarella cordifolia*). By contrast, the communities of the younger areas, where the forests are attributed to post-glacial immigration, exhibit only about half the number of arboreal species in the forest canopy, and the subordinate layers are floristically far less varied.

The mixed mesophytic forests occupy a relatively small area and are regarded as the lineal descendants of the Tertiary forests surviving in areas that have escaped glaciation, especially in the southern portion of the Appalachian plateau. The oak-hickory and oak-chestnut communities are held to represent local segregates from the mixed mesophytic type associated with more arid conditions. The communities occupying the largest areas are the hemlock-white pine northern hardwoods, covering a vast extent in the Great Lakes region, and the evergreen forests of the south-east, which are here included in the deciduous forest formation because their affinities are held to be closest with the other forest types dealt with.

For all the communities the author furnishes data from a number of sample areas respecting the woody constituents, and though reference is made from time to time to the herbaceous vegetation this is incidental rather than a feature of the main theme. The whole work is well illustrated by some eighty half-tone reproductions and nine maps, one of which is on a large scale, showing the limits of the forest regions as here defined.

The approach is essentially floristic rather than ecological, and habitat conditions are only briefly and generally treated; but within these limitations the work constitutes a valuable addition to the literature dealing with the arboreal vegetation of this area. E. J. Salisbury

CIVIL ADMINISTRATION IN GREAT BRITAIN

The Civil Service Today
By T. A. Critchley. With an Introduction by the Rt. Hon. Lord Beveridge. Pp. 150. (London: Victor Gollancz, Ltd., 1951.) 12*s*. 6*d*. net.

Mr. T. A. Critchley in this book has set out to give a factual and objective account of the Civil Service in Great Britain and the way it works, as well as to indicate in what respects it differs from the pre-war Service. This was done for the administrative class ten years ago by H. E. Dale; but Mr. Critchley covers a wider field and, it must be admitted, his book is by no means easy reading. He succeeds in conveying a clear picture of the way in which the Civil Service has grown with the increasing demands on government for positive rather than negative functions, and of the way in which certain of its inherent weaknesses are linked to such measures for obtaining public control and ministerial responsibility as the parliamentary question. But something much more vivid than the few flashes he gives of four or five Civil servants at their daily work will be required to hold the interest of the many whom he is trying to convince as to the necessity for a Civil Service and the way its size is determined by the public demand for services; and to any thoughtful reader the picture he presents of the complexities of administration is as frightening as that which he gives of the extent to which the Civil Service now touches, and sometimes paralyses, the whole of civil life.

This is not nearly as profound a book as either Mr. H. E. Dale's or the more recent studies of Dr. E. N. Gladden or Mr. H. R. G. Greaves, though it could easily have had a wider appeal. On the whole, Mr. Critchley is too much on the defensive, and what he does not say is sometimes more significant than what he actually writes. A working Civil servant could after all have scarcely been expected to write the obvious rider as to the effect on the Civil Service, not to mention on Parliament and ministers, of overloading Parliamentary sessions with legislation, however admirable individual measures may be and no matter how much public support they receive. Disregard of administrative limitations may be as disastrous as disregard of known chemical or physical properties in technical development.

Even where Mr. Critchley might be expected to be less inhibited he is too reserved. More should have been said of the Whitley Council system in the Civil Service, on the real weakness of which he merely touches. Further, though he admits that Civil servants are not infallible, he is inclined to lay the blame for defects entirely outside the Service. Of local government he says little and that little is disparaging, betraying no hint that in the revivification of local government might be found the way to a solution of the problem of complexity at the centre. He questions, in fact, the value of devolution, and when he writes of the necessity for a real spirit of public service he is plausible rather than persuasive in arguing that by this means deficiencies in organization would be corrected.

Unquestionably more mutual understanding between the Civil servant and the public is required —and, also it might be added, a clearer appreciation of the limitations of the Civil Service on the part of Parliament and Cabinet. Mr. Critchley's book may do something to further that understanding, but the dominant impression it leaves on the mind of the reader is the necessity for some very clear thinking about not so much the organization and functions of the Civil Service but rather the whole structure and organization of government, and the imperative necessity for grappling with that problem of local government reform which all political parties seem determined to ignore or avoid.

There are three other points that will strike the man of science who reads this book. Mr. Critchley clearly believes that there is room for the wider diffusion of scientific methods throughout the Service and that such a step would have a tonic effect. Nevertheless, he is sceptical as to the effect on a democratic system if the man of science once comes to dominate, and he becomes confused when he refers to the man of science or other expert as an administrator. Much more dangerous to democratic institutes, however, is the tendency for parliamentary democracy under the conditions depicted by Mr. Critchley to pass into tyranny of the executive. It is clear from this book, that that danger is yet to be removed.

The third point that emerges from the figures given by Mr. Critchley and the general picture he draws is of the extent of the demand which present conditions make upon Great Britain for trained man-power. Can the nation afford to devote to non-productive tasks its highly trained men and women in the numbers required to execute the tasks now placed upon the Civil Service? Can the educational system of Great Britain supply the necessary administrative talent, even if we draw freely on all possible reserves of it from science and technology? These are but a few of the questions raised by a book that, purporting to be descriptive, is highly suggestive to any thoughtful reader and, for all its limitations, covers the ground at least as well as any other. R. Brightman

Elements of Optical Mineralogy

An Introduction to Microscopic Petrography. By Prof. Alexander N. Winchell, with collaboration of Prof. Horace Winchell. Fourth edition. Part 2: Descriptions of Minerals, with Special Reference to their Optical and Microscopical Characters. Pp. xvi+551. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1951.) 100s. net.

THE fourth edition of Part 2 of A. N. and H. Winchell's "Elements of Optical Mineralogy" follows the third after an interval of eighteen years. During this period important developments in mineralogy have resulted from the intensified X-ray study of crystals, leading not only to increased knowledge of crystal structures, but also to a better understanding of variations in mineral composition, and to a revised classification.

As in previous editions, the book includes descriptions of all minerals the optical properties of which are sufficiently well known to permit diagnosis by means of a microscope. In bringing the work up to date, emphasis has been laid especially on the properties which serve this purpose; but details of the crystal structure of individual minerals as determined by X-rays are also given.

In the third edition, while the primary classification was chemical, the silicates were subdivided, so far as the knowledge of the time permitted, into groups on a structural basis. This system has been followed in the fourth edition; but the increased knowledge has permitted its extension to include within these groups all silicate minerals, with the proviso that the inclusion of certain minerals in particular groups is tentative. Opportunity has also been taken to bring into use the group names, tectosilicate, phyllosilicate, etc., proposed since the last edition.

This is a standard work, and it is regrettable that the increased cost of book production in the United States, and the current rate of exchange, necessitate a price that must put the book out of reach of many potential buyers.

Industrial Solvents

By Ibert Mellan. Second edition. Pp. x+758. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1950.) 96s. net.

IN the eleven years which have elapsed between the publication of the first and second editions of this work, many new solvents have been discovered or developed for commercial use, and measurements of physical properties have multiplied. It is not surprising, therefore, to find that the size of the volume has increased by more than 50 per cent.

The first 200 pages deal with solution and general properties of solvents in a manner which may appear unorthodox to physical chemists, unless they realize that the subject-matter is concerned mainly with solvents and their uses in the paint and varnish industry. A bad fault occurring here and throughout the book is the presentation of data on solubility, viscosity and rates of evaporation without any mention of temperature. Many figures given in this part are repeated later, and it is suggested that a great improvement would result from a thorough revision and drastic curtailment.

The remainder of the book contains a vast amount of information of most diverse nature regarding the properties and uses of some four hundred liquids and their mixtures. Numerous commercial solvents are included and their composition indicated. Some of the data recorded appear to be of little value, while an item of real interest, the price of the solvents, has been omitted. Minor criticisms apart, however, there is no doubt that this volume, with its wealth of information collected from sources which are in many cases inaccessible to the average reader, must be regarded as indispensable to all those whose work involves the use of organic liquids. H. E. WATSON

The Technology and Chemistry of Alkaloids

By Frank E. Hamerslag. Pp. viii+319. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1950.) 48s. 6d. net.

THIS book is primarily intended to assist those engaged in the manufacture of alkaloids. It is therefore principally, but far from exclusively, concerned with processes of isolation (or synthesis) and purification. Following a brief description of general procedures and technical equipment, the commercially practicable alkaloids are discussed in turn, either as individuals or as related groups, in eighteen chapters. Each chapter contains some discussion of the structural chemistry, the natural sources, the pharmacological properties and the means of identification of the appropriate alkaloids, in addition to a description of the manufacturing methods used. It is probably in this last respect that the main value of the book emerges, for the author is able to draw upon his personal experience in order to evaluate procedures, to give practical advice and to make specific recommendations. The detailed descriptions given of the methods of isolating individual alkaloids certainly merit the attention of all who have occasion to undertake these operations. The book is equipped with a comprehensive index and the text is liberally supplied with references to the original literature.

The Thought of C. S. Peirce

By Prof. Thomas A. Goudge. Pp. xiv+360. (Toronto: University of Toronto Press; London: Oxford University Press, 1950.) 40s. net.

THE life of Charles Sanders Peirce (1839–1914) presents the world of scholarship with a problem at once profound and fascinating. Prof. Goudge, in writing this distinguished book, sets out to explain why this should be, and what can be learnt from it. Essentially, Peirce was an example of ambivalence; he was capable of an enviable analytic power at times (perhaps mostly) overwhelmingly naturalistic, at other times completely transcendental. If a conclusion is permissible regarding a life so fruitful and yet lived so dangerously, it is that his naturalism triumphed in his mind, his transcendentalism in his heart. This entailed a certain rigidity of partition between theory and practice, exemplified by the extremely abstract character of his thought when functioning as a philosopher or logician, alongside a thoroughly competent, almost mundane, affection for experimental chemistry, in which subject he graduated *summa cum laude*. When to all this is added more than a touch of the poet and the mystic (making him accord to æsthetics, for example, an exalted place in his hierarchy), it is clear with what a unique mind we are confronted.

Prof. Goudge shows a sure touch: he lets the restless intellect of Peirce shine through, without the interposition of a biographical screen. An excellent memoir is the result, full without being repetitious, understanding yet critical. F. I. G. RAWLINS

A HUNDRED YEARS OF PLANT MORPHOLOGY*

By Dr. H. HAMSHAW THOMAS, F.R.S.

IN 1851 British botanists were still mainly occupied with the description and classification of plants, studies which were very similar to those which had been carried on since the days of William Turner in the sixteenth century. The work of men like Grew, Hales, Bradley and Knight, who realized the interest of plant physiology and plant biology, had exerted little influence on the main current of botanical thought; in fact, these men were not generally regarded as botanists. Botany was studied only in the field, the garden and the herbarium; botanical laboratories did not exist, and teachers like Henfrey and John Hutton Balfour (known to his students as "old woody fibre"), who attempted to develop anatomical study with the aid of the microscope, had met with little success.

At the time of the Exhibition of 1851, many of the outstanding botanists of the early nineteenth century were still living. Robert Brown, in his seventy-eighth year, was president of the Linnean Society; Sir William Hooker was director of the Royal Botanic Gardens, Kew; John Lindley was professor in University College, London; J. S. Henslow, Darwin's teacher, still held the chair of botany at Cambridge but was also rector of Hitchin and only resided in Cambridge during the Easter term; Sir Joseph Hooker had just returned home from his Himalayan journey, and Charles Darwin was quietly working at Downe on Cirripedes and brooding over the 'species question'. Modern botany was being actively developed in Germany by von Mohl, Nägeli, Hofmeister and others who had been stimulated by Schleiden; but it had very little influence in Britain. It is remarkable that there is no reference in the "Origin of Species", the letters of Charles Darwin or the published letters of Sir Joseph Hooker, to Hofmeister's "Comparative Researches on the Higher Cryptogams and Gymnosperms" which was published in 1851, and demonstrated the existence of an alternation of generations in these two groups—a powerful argument for the idea of evolution. This work was, however, translated into English and published by the Ray Society in 1862.

The outlook on plant structure in 1851 was that commonly held before the coming of the doctrine of evolution. Each species was believed to be the result of a separate act of creation; it had a form and structure which distinguished it from other plants. But among the great diversity of form it was possible by the exercise of the mind to recognize certain unifying principles. A mental picture of an ideal plant might be formed to serve as a standard with which all actual living forms could be compared. Goethe and the German Nature philosophers of the early nineteenth century formulated different concepts of the ideal plant, but Goethe's was the only one of lasting value. This was an imaginary organism consisting of a stem bearing a series of leaves showing various types of metamorphosis, or conceptual change, and having roots below the ground. Goethe's new science of morphology made considerable progress. We find Lindley expounding it in 1832 in his "Introduction to Botany". In 1857 Henfrey, in his "Elementary Course of Botany", writes: "the study of the metamorphosis of the organs of the flower is now advanced far enough to set all general questions at rest". Although his treatment of morphology and comparative anatomy is mainly descriptive, Henfrey defined this branch of botany as having the object of ascertaining what are the elements of plant organs, and of tracing out the laws under which they acquire the different forms presented in fully developed plants.

The publication of "The Origin of Species" in 1859 gave a new impetus and a change of direction to the comparative study of plant form. While Darwin himself did not claim that the parts of flowers had arisen in evolution from leaves of a uniform type, he mentioned that "almost everyone is familiar with the view that the floral parts are metamorphosed leaves". At first there seems to have been no change in botanical studies; but a great revolution in the outlook of botanists took place between 1870 and 1880.

The leaven of the concepts of evolution, the work of the great German plant scientists, the genius and energy of Prof. T. H. Huxley, the Education Bill of 1870 passed by Gladstone's Liberal Government, all combined to produce far-reaching results. Huxley had been teaching in South Kensington in buildings resulting from the 1851 Exhibition, and he undertook the organization of classes in biology to train teachers in science for the new public elementary schools. These classes included adequate practical work, an innovation in Britain at the time. Studies of a taxonomic kind were subordinated to the teaching of anatomy, physiology and the life-histories of plants. Thiselton-Dyer gave the first course in botany in 1873, assisted by Lawson of Oxford, Vines came from Cambridge as an assistant in 1875, and later Hillhouse, Daniel Morris and Bower took part in the teaching. Before long, teaching with laboratory work on the same pattern was begun in several British universities. Lawson began at Oxford, Vines, although not holding the chair, organized classes at Cambridge, Hillhouse went to Birmingham, and Bower to Glasgow. Dyer played a large part in the foundation of the Jodrell Laboratory at Kew, where much important work in plant morphology and physiology has been carried out.

The establishment of the Normal College of Science, which later became the Imperial College of Science and Technology, was a very important event in the history of botany in Britain. It produced a small band of enthusiastic teachers and investigators, two of them responsible for my own interest in botany, and it led to considerable activity in the investigation of plant form and structure.

At the outset, the exponents of the new botany concentrated on the objective study of all aspects of plant life. The great text-book by Sachs was translated into English and published in 1875. It contained little morphological theory; but plant structure was treated in some detail with frequent reference to the development of organs and their physiological implications. This book aided the new movement. But very soon the minds of biologists began to be influenced more and more by the ideas of evolution, and the establishment of phyletic relationships became one of the chief endeavours of many British botanists.

---

* Substance of a paper entitled "Changes in the Outlook on Plant Structure during the Past Hundred Years" read on August 9 before Section K (Botany) at the Edinburgh meeting of the British Association.

Between the years 1880 and 1910 the study of plant structure was dominated by the belief that it held the key to the problems of phylogeny. Attention was mainly paid to the Pteridophyta and Gymnosperms, the possible connexion of which had been indicated by the work of Hofmeister. This climate of thought was intensified by the striking discoveries in Britain of fossil plants with well-preserved structure. These were especially due to W. C. Williamson, who was appointed professor of natural history in Owen's College, Manchester, on its foundation in 1851. Between 1868 and 1895 he described the structural details of many interesting and novel forms from the nodules of the coal measures of Lancashire and Yorkshire, and showed how some ancient pteridophytes were trees with secondary thickening. This and other contemporary work directed attention to the importance of this group in the vegetation of ancient times, while the structure of the stems called *Lyginopteris* and *Heterangium* suggested a connexion between the ferns and cycads.

All this historical evidence of evolution based on anatomical structure made a profound impression on the younger botanists of the time and many of them became active investigators. D. H. Scott, who was keeper of the Jodrell Laboratory, became associated with Williamson and afterwards continued to describe the structure of fossil plants; Kidston as an amateur began his detailed investigation of the Carboniferous plants of Scotland; Seward studied with Williamson at Manchester, and then specialized on the plants of the Mesozoic period; Oliver, working with Scott, established the characteristics of the Pteridosperms, and later added greatly to our knowledge of fossil gymnosperm seeds. At the same time, our knowledge of the living pteridophytes was being greatly extended, especially by Bower, who devoted his long life to the investigation of this group.

It would be difficult to exaggerate the importance of this period in the acquisition of factual knowledge, though the general trend of thought of the time is open to criticism from the philosophical aspect. For some twenty-five years it was assumed that Goethe's morphology could be forced into an evolutionary frame. As Dr. Agnes Arber so aptly writes, "by a feat of legerdemain, which seems to have passed almost unnoticed, the Ancestral Plant was substituted for the Archetypal Plant and those characters which had, with reason, been attributed to the mental conception of the archetype were, without further justification, assumed to have been proven for an actual historically existent ancestor". This point of view was encouraged among botanical students in Britain by the earlier translations of Strasburger's "Text-book of Botany". For a long time it proved a real stumbling block to the understanding of the fossil record, as well as creating an unbridgeable gulf between the Thallophyta and the Cormophyta.

The preoccupation of British botanists with the cryptogams and gymnosperms led to the realization of the value of anatomical characters in the study of plant morphology, a view that was regarded as heretical by the German botanists. It resulted, however, in considerable neglect of the flowering plants. Before 1920 almost the only extensive series of investigations in this group was the study of seedling structure under the leadership of Dr. Ethel Sargant. At first the aim of this work seems to have been mainly phylogenetic, but as it progressed Hill and De Fraine, and also Compton, were led to recognize the importance of physiological and ecological considerations.

The growth of the study of ecology, genetics and cytology towards the end of the first decade of this century diverted the attention of many young botanists from the pursuit of phyletic morphology. These subjects, as well as physiology and physiological anatomy, caused the problems of plant structure to appear in a new light. Bower's great book on "The Origin of a Land Flora" (1908) introduced biological considerations into morphological discussion and thus initiated a break with tradition; hitherto plant anatomy and morphology had been completely separated from physiological considerations.

From this time onwards there was in Britain a steady weakening of the view, expressed in Strasburger's text-book, that phylogeny is the only real basis of morphological study. This dictum was severely handled by Prof. W. H. Lang in his address to Section K of the British Association in 1915. He advocated a wider view of the significance of plant structure gained from the study of parallel developments, the methods of advance in different groups and in different generations of the life-cycle, the changes observable during development and the results of experimental treatment. Though this causal outlook is essentially different from the historical outlook, there is no opposition between causal and phyletic morphology. It has to be recognized that "there has been an evolution, not of mature plants, but of specific substances exhibiting development". Owing to the First World War, this admirable address probably received less attention than it deserved. A few years later Kidston and Lang published their full account of the plants of the Rhynie Chert, and opened up new lines of thought on plant evolution. They described very early plants which were completely different from the *Urform* of Goethe; and Lang's later work on the Silurian and early Devonian forms, together with that of Halle, Krausel and Weyland, showed that these forms were typical of the early cormophytes.

At the meeting of the British Association in Edinburgh in 1921, Dr. D. H. Scott as president discussed the phyletic implications of the recent discoveries in the Rhynie Chert, while Prof. Bower developed the causal side by a very interesting paper on size and form. Some of us who were present felt that, from these two aspects of morphology, real progress was being made; but the great problem was the bearing of this new knowledge on the morphological study of the flowering plants.

It seemed to me in 1932 that we should make no progress until we recognized clearly that Goethe's concept of metamorphosis had no evolutionary significance: for this reason I suggested that a fundamental distinction existed between the old morphology and the new. But this opinion has gained adherents very slowly. In the period between 1925 and 1939 Miss E. R. Saunders carried out a series of researches on the vascular structure of angiosperm flowers with the view of elucidating the evolution of carpels. While adding considerably to our factual knowledge, the value of her conclusions depends on the validity of her premises, and it seems doubtful if her basic suppositions were justified from a historical point of view. On the other hand, the work of Dr. Agnes Arber shows that most valuable results are forthcoming by strict adherence to the philosophical system of the old morphology. Many people now find this approach to the study of form difficult to understand owing to our changed outlook on natural objects. They may have read papers like the admirable address on the interpretation of plant structure delivered to Section K of the British Association in 1939 by Prof. D. Thoday, and cannot envisage a system of thought from which biological and physiological considerations are excluded.

A survey of the changes in outlook since 1851 seems to show that form and structure can be viewed from three separate aspects: the old, abstract and purely intellectual approach; the causal and developmental point of view; the objective and historical study of plant evolution, which is, perhaps, still undeveloped as a logical system of thought. While these three branches of study will probably be best developed as separate disciplines, I believe that their results will eventually contribute to a synthesis of far-reaching importance.

GEOGRAPHY IN THE SERVICE OF MANKIND*

By E. O. GIFFARD, M.B.E.

A LAYMAN is not the right person to review the academic evolution of geography or to put forward detailed proposals for its further development as a scientific study: such matters must be left to those properly qualified to deal with them. A layman, however, may quite properly examine the record of the services of geography to the common people, and, indeed, may also be a proper person to urge that geographical knowledge shall be more frequently and widely applied in the conduct of both national and international affairs.

It is commonly said that 'pure' scientists are not concerned with or about the use made of the knowledge which they accumulate. Results, in their case, are said to be sufficient if it can be proved that something has been added to the store of human knowledge. This familiar argument is, of course, basically sound; but it appears to overlook the fact that, in the last analysis, a man of science is a specialist or expert employed in the service of his fellow-men. That is to say, he is, directly or indirectly, a servant of the public. Now the public is accustomed to assess the value of any study or activity by an analysis of its observed or deduced results. If the results appear to be good, then the study or activity in question continues to command respect and support and the specialists and experts concerned enjoy a high reputation. If, on the other hand, the results appear to be unsatisfactory or if, after a reasonable time, no results can be seen or deduced, then the value of the particular study or activity becomes suspect and the support accorded to its practitioners is liable to be diminished. For these reasons it is submitted that men of science and particularly geographers cannot afford to remain entirely disinterested in the use made of their knowledge and ought to do whatever they can to encourage its useful application.

As has been said, the public tends to evaluate a study or activity by its visible, demonstrable or deducible results. In this connexion the words 'visible and demonstrable' are particularly important. Remember the wisdom of those who insisted that justice must not only be done but must "manifestly be done". If public respect for scientific work is to be maintained at a high level and if financial support is to be forthcoming on an adequate scale, then the results of such work must be manifest. In this connexion the increasing dependence of our universities upon the public purse is not to be forgotten.

Results sufficient for the purpose need not, however, be directly produced by those who accumulate the required knowledge. It will serve well enough if they are usually produced by laymen who know how to use the knowledge or the techniques supplied by the professional experts, provided always that the experts receive adequate credit for the vital part they have played.

Compared with many other scientific workers or experts, the geographer is somewhat handicapped in the matter of producing visible or demonstrable results. The physicist, for example, lacks no publicity for the results of his labours, nor does the chemist or the engineer. The geographer, however, like the economist or the psychologist, deals largely in ideas which can rarely, if ever, be translated into anything which can be seen except upon paper. Perhaps he is a little better off than the economist and certainly he is better off than the psychologist, because the geographer at least has the solid earth as the subject of his study, whereas the psychologist is concerned with the invisible and intangible thought processes of the human brain. Nevertheless, the geographer creates few visible evidences of his work and it is not often possible for the layman to pause and point and say "that was done by a geographer".

Since geographers are not, in the ordinary sense of the words, either producers or administrators, since they do not till the soil, fish the seas, labour directly in industry, engage in trade or direct the energies of those who do these things, their contribution to the common effort and the common weal has to consist, on one hand, of learning and recording things about the earth as the home of man and, on the other, of teaching and advising. For visible results the layman has to be content with books and maps and things on paper: for other results he must rely on deduction rather than sight. In other words, he must look for abstract rather than concrete evidence. Naturally enough, he thinks of the geographer (when he thinks of him at all) as the informer, teacher or adviser, and he thinks he ought to be able to detect the influence of the geographer in many departments of human affairs. Nor is it unreasonable that he should do so. As practitioners of a subject which can claim no less than twenty-one academic chairs in Great Britain alone, as intellectuals equipped with special knowledge about the home of man, geographers ought surely to be found exerting a profound influence on the conduct of both national and international affairs. What are the facts?

Outside the universities and the schools, geographers are held to be of small account. In the departments of State, in local government, in industry and commerce and in the Fighting Services they are almost unknown. That surely must be very disappointing, if not humiliating, to professional geographers. Certainly it is a thought-provoking fact to laymen. Admittedly geographers have served on one Royal Commission (the Royal Commission on the Geographical Distribution of Industry) and may have served on others though not specifically as geographers. Some have served on the staff of the

---

* Substance of a paper read on August 10 before Section E (Geography) at the Edinburgh meeting of the British Association.

Ministry of Town and Country Planning (now known by another name, but, like the rose, retaining the same odour), and a few have been appointed to similar posts in local government. A few may be serving in administrative posts in the Dominions and Colonies, and it is possible that one or two are to be found as advisers in industry and commerce. Some there are, of course, serving with distinction in the Fighting Services, but few of these serve as geographers. In truth, the number of qualified geographers employed as such in any sphere of administration or in any public service may fairly be described as negligible. Only as teachers in the universities and schools may the qualified geographer be found in fair numbers, and sometimes, even in such places, he still has difficulty in maintaining his status and dignity as an important specialist.

It is clear, therefore, that, if geographical influence has been brought to bear on problems of the day, it has been largely exerted by laymen. We know, of course, that laymen do apply geographical knowledge daily in matters great and small; but there must be very few laymen in positions of authority whose knowledge and appreciation of geographical principles are equal to the requirement. Unfortunately, also, laymen making use of geographical knowledge are often not very sure what sort of knowledge it is that they are using, and very few of them ever pay tribute to the people from whom they obtained it. Thus the professional geographer rarely gets any credit and, unless he is a school teacher, he remains in the background—a vague, shadowy figure whose function remains largely a mystery to the layman.

Are things any better elsewhere? Let us see what those who ought to know say about the state of affairs in France. M. Georges Chabot, professor of geography in the Sorbonne, agrees with M. Louis François, inspector-general of public education in France, that "The Public is largely ignorant of Geography and the Press is in the same state": and that in France, which has produced some of the greatest geographers of all time. In Germany, where geography was once held in the highest esteem, the subject is making progress towards revival but has had to pay heavily for having allowed itself prior to 1939 to become the tool of political gangsters. In the United States geography is alive, and geographers are more vocal than in Britain; but convincing evidence of intelligent application is lacking or difficult to find. As for American politicians, they pay lip service to geography but their actions sometimes justify doubts as to whether they fully understand what they praise. In other parts of the world the situation seems to be the same or not so good. The truth is that, although geography has marched forward in the universities and the schools of a great many countries, it remains barely noticed by statesmen and administrators and is largely ignored by the average, adult citizen.

In the British Commonwealth great problems arise almost weekly which demand the assistance of the best brains and the wisest heads; but though quite a number of these problems lie well within the legitimate field of the professional geographer, he is seldom consulted. What, perhaps, is more deplorable is that geographers themselves do not seem to exert themselves to make their influence felt. Far-reaching political and economic proposals are widely debated in Britain in connexion with which the qualified geographer could render signal services by contributing his knowledge and stating his convictions, and yet never, or scarcely ever, is his voice raised loud enough or in time to affect the issue. Charged with indifference or sloth in these matters, some geographers have said that it is not consistent with their position or their dignity to join in political or other public controversies. It is here submitted that such an attitude is wrong. To remain aloof, withholding vital information or advice merely because no one has thought of asking for it, is equivalent to issuing an invitation to be ignored. Unfortunately, there are many who, for one reason or another or for no reason at all, fail to seize the opportunities for service which offer themselves. We may find in that fact one of the reasons why geography lacks its fair measure of public esteem and support and why so few geographers are to be found in positions of influence outside the academic field.

It is one hundred years since Section E of the British Association was established. By now geographers should be able to point with proper pride to the achievements of their kind in administration and public affairs. There should be trained geographers employed, at least as advisers, wherever geographical knowledge is essential to wise decisions and intelligent action. The simple fact that geographers are so rarely to be found occupying such posts is evidence enough that geography has not yet become the force which it ought to be. Geographers have knowledge which contains the seeds of a great power for good. Wisely disseminated and applied, that knowledge might yet do much for mankind and for the peace of the world. It is time that that knowledge became more widely known and used, and it is more than time that geographers took action to make it so.

That the study of geography has done good and has accomplished much would not and could not be denied by any intelligent person who cared to give the matter careful thought. The great wealth of information which has been so patiently collected, analysed and recorded in the forms of books, papers and maps is irrefutable evidence of the skill and industry of practitioners of the subject. In the practical sphere the record of exploration and of research work in the field is a record of which geographers may justly be proud. In the schools of Great Britain the teaching of the subject has been revolutionized, and slowly but surely it has gained status and respect despite many handicaps and a good deal of unreasoning opposition. In the universities, as we all know, the subject has advanced beyond the most sanguine hopes of those who laboured fifty or more years ago to obtain for it a bare foothold. Yet, despite these achievements we cannot pretend that things are satisfactory. The authors of the Unesco pamphlet entitled "Towards World Understanding" have felt obliged to write ". . . in spite of the progress of geography in methods of research and dissemination, the efforts of geography teachers produce disappointing results". Again, in the same pamphlet they go on to say, ". . . actually less is known of geography to-day than formerly". We may question the accuracy of these statements; but it is impossible to deny that the mere fact that a number of distinguished geographers and teachers can agree to make them is alarming.

Another thing which is disquieting is that, despite the brilliance of many of the teachers and the interesting manner in which the subject is presented in so many schools, pupils are not generally enthusiastic about geography. It is safe to say that, in most cases, geography is the subject which promising pupils want to drop when they are approaching the period in school-life when something has to be given up to allow for more intensive study of other subjects. In this readiness to drop geography towards the culmination of the school course and in the desire to avoid taking it in the examinations, the more brilliant pupils are all too often encouraged by head teachers, who seem prone to share the pupils' lack of interest in the subject. What can be the explanation of this? It is submitted that the explanation is the same as that already suggested as being the cause of apathy in the adult citizen, namely, lack of evidence that geography is something applicable to life. Children can see daily evidence of the application of physics, chemistry, mathematics, biology and engineering, but they rarely see or hear anything in the world outside school which would lead them to believe that geography is something that really matters. As we have already said, geographers create few if any visible monuments, are rarely heard, seldom reported and are not often seen at work in a way which renders them recognizable to laymen as geographers. As more than one senior pupil has said to me: "You never hear of anybody *doing* anything with geography: it's just a school subject". Those pupils had the wrong idea, of course, but can we blame them? Geographers rarely speak in Parliament or in the local council chamber. Comparatively few of them give lectures to the general public on the problems of the day: very few are heard on the wireless, and then, as a rule, only on the Third Programme. They are practically never alluded to in films, even incidentally, and they almost certainly occupy less space in the newspapers than other scientific workers. Thus there is little indeed to indicate either to the adult or the adolescent citizen that geographers exert any influence or do any notable service.

To no one would this sorry state of affairs give greater distress than to that great geographer and public servant, Sir Halford Mackinder, were he alive to-day. Mackinder, perhaps more than any other great geographer, believed in the application of geography to world affairs; that is to say, he believed in it being not only studied but also used for helping to solve some of the problems of mankind. He saw it as a power for good and believed that, properly applied, it could help the statesmen of the nations to agree on wise and practical territorial arrangements which would remove some of the more potent causes of war. He saw it as at once both a science and a philosophy and also as a technique which could be applied to a great variety of human problems—local, national and international. Had geography been so used it could not now appear to so many ordinary people as the purposeless and almost barren study which to too many of them it seems to be to-day.

Fortunately, signs are not altogether wanting that some geographers of standing have at long last sensed the need to explain their purpose and demonstrate their techniques to educated laymen. Some also seem to be awakening to a more proper appreciation of their responsibilities as workers in the social and political fields. Even since the first draft of this paper was written there have been some significant developments in this direction, and they are to be welcomed. Unesco has done a service to geography by indicating its possible application to the problems of world understanding and by exposing the failure, up to the present, of geographers generally to gras their opportunities in this connexion. Finally mention must be made of the Land Utilizatio Survey which, whatever criticisms may be justl levelled against it, represents a gallant and largel successful attempt to apply a geographical techniqu to a social purpose.

In regard to the application of geography, let u contemplate only a few of the things geographer could do now. They might, for example, turn thei minds to some of the pressing territorial problems which threaten the peace of the world instead o concentrating their studies upon areas or regions which, however interesting academically or useful as subject for an exercise, are not in the minds of the public and are not storm centres of the day. They might usefully express views on the great problem of the production and distribution of raw materials. They might put forward a constructive scheme, based on sound geographical principles, for the amendment of the areas or regions of local government in Britain. They might give us soil maps. Other things in which we are all interested are (to take only a few instances at random): better plans than exist at present for the re-distribution of the urban population; the better development of Commonwealth resources; the future of Africa and particularly of parts of that continent; and the great problems of world over-population. Indeed, there are a score or more of golden opportunities for the geographer to make his mark and prove his worth in contemporary affairs. Cannot some of them be taken? Perhaps the answer will be given that they have been taken. If so, then the work which has been done must be hiding in the pages of some professional journal or in the archives of some university or learned society and has not yet been brought to the notice of the world at large.

As to the employment of geographers in the departments of State and in the public services, we cannot hope for much improvement in the present position until geographers have succeeded in establishing themselves more securely in public esteem; and they can only hope to do this by making themselves useful and by letting the world see or hear about their good works. In this connexion it would be helpful both to geographers and laymen if the great daily newspapers would appoint qualified geographers as special correspondents. If that were done, the views of geographers would be more often quoted and the value of their special knowledge would be more widely appreciated.

These latter years have witnessed the development of a number of geographical sects—each sect preoccupied with one particular aspect of geography and each sect waging a kind of cold war against the others. Indeed, not infrequently of late, it has seemed that sectarian interests have been allowed to rise superior to the good of geography as a whole. That there should be some workers in the field who are more interested in one part than in the other parts is natural, necessary and good; but it is not good for such persons to be allowed to proclaim that the part in which they happen to be most interested is the part which matters most. Nor is it good that such persons should be allowed to pour contempt on the special work of others. The part cannot be greater than the whole, and when anything is compounded of parts, as geography is compounded, every part is essential, for, missing a single part, the whole cannot exist.

It is submitted that the professors, who are the academic leaders, would be wise to bring all their influence to bear against those who, either with intent or inadvertently, would break up the synthesis into its component parts and, this done, would seek to proclaim themselves the high priests of their particularly favoured mysteries. That way lies disintegration and disaster. Let there be controversy by all means; but let it be conducted in an atmosphere of mutual respect and always with the main object of furthering the study of geography as a whole, rather than of any one part of it. Let the elder statesmen of geography exhibit a unity of fundamental ideas and a determination to maintain an essential discipline.

In 1931 Mackinder forecast that, towards the middle of the twentieth century, geographers would have their golden opportunity. He said: ". . . then will be the opportunity of the geographer-statesman, for geography must underlie the strategy of peace if you would not have it subserve the strategy of war". Unheeded by too many, that hour has struck! The geographer, that is to say the person trained to think geographically, is better equipped than most other people to see through the fog of political propaganda and the mists of emotional nationalism and to discern the real, underlying causes of discontent and disturbance. Could the geographer but bring his influence fully to bear in the counsel of the nations, could he but gain for his knowledge and skill the respect which both so richly deserve, there would be at his command a power which might do much to ensure fair and just territorial settlements, bring about a more equitable distribution of the world's natural wealth, promote better understanding between peoples and remove some of the more potent causes of wars. That, indeed, would be service to mankind. That power, however, will not be granted to geographers until they have given more abundant proof of their qualities and capabilities and of the usefulness of their special knowledge.

VARIATIONS IN BROOD-STRENGTH IN THE NORTH SEA HADDOCK, IN THE LIGHT OF RELEVANT WIND CONDITIONS

By Dr. J. N. CARRUTHERS,
Commander A. L. LAWFORD, R.N. (ret'd.),
Instructor-Lieut. V. F. C. VELEY
Hydrographic Department of the Admiralty
AND
B. B. PARRISH
Marine Laboratory (Scottish Home Department), Aberdeen

MANY years of research into the biology of the haddock (*Gadus æglefinus*) in the North Sea have shown that one of the major factors contributing to the short-term fluctuations in the fortunes of the commercial fishery for this species is the varying numbers of recruits entering the fishable stock from year to year. The importance of this phenomenon was firmly established during the early inter-war years by Thompson[1] (then of the Marine Laboratory, Aberdeen), who, from the results of extensive research vessel trawling surveys in the North Sea, was able to relate the fluctuating yields from the fishery to this cause. These surveys, which were afterwards extended by Raitt and later by Parrish (of the same Laboratory), gave estimates of the distribution and relative density of each brood of haddock throughout its demersal life and thus gave measures of the relative stock strengths from year to year, and provided a means for forecasting, a year in advance, the relative success of the commercial fishery. The magnitude of the fluctuations in brood-strength over the period 1920–49, exclusive of the war years 1939–44, are illustrated in Fig. 1. This gives the mean annual catch per hour of fishing relative to that in 1923, rated as 10, taken with the trawl of the research vessel for each successive brood in its second year of life, by which time its members have become demersal.

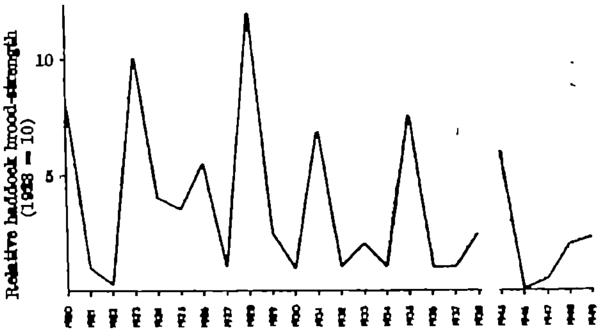

Fig. 1. Fluctuations in haddock brood-strengths in the North Sea, 1920–49

In an attempt to assess the factors causing these fluctuations, the first step which had to be taken was to determine that critical stage in the haddock's development, up to the end of its second year of life, during which the observed fluctuations in abundance may be experienced. The possibilities may be summarized as follows: (1) variations in egg production from year to year; (2) annual changes in the survival-rates of eggs, larvæ and young fish during the pelagic phase; (3) annual changes in survival-rate after the demersal stage has been reached.

In a paper read before the Challenger Society in 1949 (now in preparation for publication in detail) an analysis was made of the large volume of data of the distribution and density of each brood in its first and second years of life, and of the egg production potential of the spawning shoals from year to year during the period 1920 to 1949. This has yielded the following results: (1) variations in abundance of successive haddock broods cannot be properly attributed to corresponding variations in egg production potential of the spawning shoals; (2) no large-scale differential mortality can be traced after the haddock become demersal and before they reach trawlable size.

These results lead to the important conclusion that the factors determining the level of recruitment are operative during the pelagic phase of the haddock's life-history. These factors must, therefore, be sought among the complexity of physical, chemical and biological features of the pelagic environment in which the eggs and larvæ develop, and for most of which no serial observations over a wide enough area are available.

Of these features, one which has received much attention in the marine field and has been considered to be critical for the survival of many species of organisms is the current system of the upper-water layers, within which the spawning products develop and are distributed by its changing speed and direction into areas favourable or unfavourable for subsequent development. The possible importance of such changes to the survival of haddock in the North Sea is apparent from a knowledge of the disposition of the spawning area in relation to the surrounding water masses. Spawning takes place in the northern North Sea basin, chiefly within the boundaries of the large elliptical eddy system described by Tait[2], which to the north and east is bounded by deep-water masses, the movements of which are northerly or north-easterly in direction. Any spawning products driven into these waters will, therefore, be swept away from the North Sea along the Norwegian coast. Those driven to the west and south, on the other hand, will be distributed over the main body of the North Sea, which constitutes the main haddock nursery area.

Unfortunately, in the absence of precise year-to-year measures of the direction and speed of mass water transport in the northern North Sea during the spawning season, the importance of this phenomenon to haddock-brood survival cannot be assessed directly. An indirect approach is possible, however, from a consideration of the variations in the direction and speed of the local winds over the spawning area, the importance of which in influencing the direction and speed of local surface water movements has been demonstrated by Carruthers[3] and Carruthers, Lawford and Veley in a series of papers recently published. Striking preliminary results were obtained in 1938 by Carruthers[4] from an analysis of variations in haddock-brood strength and variations in the wind component from the south-east quadrant as deduced from barometric pressure data.

A more complete analysis of this relationship was made possible following the preparation by Dr. G. Dietrich, of the German Hydrographic Institute (Hamburg), of monthly wind resultants of a high degree of accuracy for the northern North Sea, covering the years 1900–49. Relative haddock brood-strengths for the years 1920–49 (exclusive of the war years 1939–44) have been used and, for each year, the wind values for the four months February to May have been taken. An account of the analysis was prepared by us and read before the International Council for the Exploration of the Sea in October 1950; on that occasion a full exposé of the underlying ideas was given, and these have now been presented in a paper, "An Attitude on Fishery Hydrography", due to appear in the United States shortly[5].

An initial analysis of these data showed that, in general, high haddock values occurred during years when southerly and easterly wind components were large, and northerly and westerly small, whereas low haddock values were accompanied by reversed conditions. In view of these results, a wind function, $H = \sqrt{S^2 + E^2} \sim \sqrt{N^2 + W^2}$ (where S, E, N, W, are the four wind components), was developed by Veley and was used in the subsequent analysis. The values of H, derived in this way, are plotted against the relative haddock values in Fig. 2. The value for $\sqrt{S_2 + E^2} > \sqrt{N^2 + W^2}$ and vice versa are plotted separately.

The conclusions to be drawn from these results are as follows:

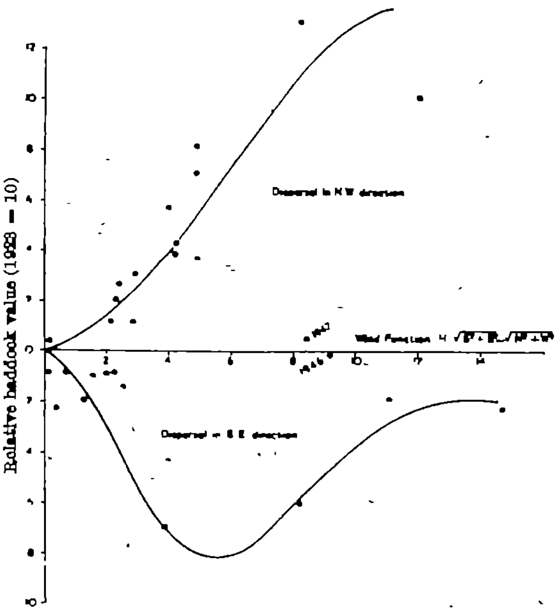

Fig. 2. Relationship between relative haddock value and wind function

(1) When the $S\ E$ term is large compared with the $N\ W$ term, dispersal of the spawning products is in a north-westerly direction. This appears to be the most favourable to brood survival.

(2) When the $S\ E$ term is small compared with the $N\ W$ term, dispersal is in a south-easterly direction. This is also favourable to brood survival, but to a lesser extent.

(3) A small value for H might arise either from a north-easterly or a south-westerly dispersal, or from no dispersal. Such a small value for H has always been found to be unfavourable to haddock survival so far, but, over the period of years investigated, a small value of H proved always to be due to south-westerly winds causing north-easterly dispersal.

The importance of these results is evident when they are considered in relation to the movements of the water masses surrounding the spawning area as outlined above. Thus, distribution in a north-westerly direction will dispose the spawning products within the eddy or, if out of it, into the southerly running stream entering the north-western North Sea from the Atlantic; this will distribute them over the main body of the North Sea, which is the main nursery area for adolescent haddock. Similarly, dispersal in a south-easterly direction is favourable unless the spawning products are driven beyond the boundaries of the eddy, when they will enter the north-going stream along the Norwegian coast and will be lost to the North Sea. Calculation shows that this is likely to take place for values of H greater than 6, which is the value at which the maximum occurs in the $S\ E$ dispersal curve in Fig. 2. Dispersal to the north-east will also drive the spawning products into the northerly-going current which runs along the eastern and northern boundaries of the eddy.

These results can, therefore, be explained in terms of the wind-induced movements of the water masses in the spawning area, and of the prevailing current systems of the surrounding waters. In the absence of precise data of the distribution of the spawning products, the validity of this interpretation has yet to be substantiated. The close relationship of the success of haddock-brood survival to the prevailing local winds during the spawning and post-spawning periods is, however, clearly demonstrated for all but two out of the twenty-four years investigated. In the years 1946 and 1947, some over-riding factor or factors must have dominated the haddock development. This may have been, for example, temperature, and it is interesting that the 1947 spawning followed one of the coldest winters in recent years. Nevertheless, it is considered that a knowledge of the wind conditions over the spawning area may lead to accurate predictions of future haddock-brood strengths, at least a year in advance of data obtainable at present, either with a research vessel or from commercial statistics, that is, two years in advance of the entry of these fish into the commercial fishing.

A fuller account of this work will be published elsewhere (Scientific Investigations, Fisheries Division, Scottish Home Department).

NEWS and VIEWS

Chemistry at Queen Mary College, London : Prof. J. R. Partington, M.B.E.

PROF. J. R. PARTINGTON retires this summer from the chair of chemistry at Queen Mary College, University of London, which he has held since 1919, and has been appointed emeritus-professor in the University. After graduating at Manchester, where he won the highest academic honours, he worked first with Dixon, and then with Nernst at Berlin, and so founded his lifelong interest in inorganic chemistry and in the physical methods for the study of chemical problems then being newly developed. During the First World War he served in the Army, and later did research work in applied chemistry for the Inventions Department of the Ministry of Munitions, before succeeding Prof. Hewitt at Queen Mary College. To his colleagues in London his outstanding characteristics are, perhaps, first his wide and scholarly knowledge of chemistry, secondly the integrity, precision and good sense with which he has always discharged his University duties, whether as examiner or as member or chairman of University boards and committees, and thirdly his lively and ever-growing interest in the teaching and exposition of chemistry.

Prof. Partington is, of course, well known for his researches on the reactions and constitution of many inorganic compounds, on the properties of gases, on electrochemical problems, on dipole moments of organic liquids, on solubility and various other subjects ; many of them are models of critical thought combined with great experimental skill. His greatest contribution to the development and spread of chemical knowledge probably lies, however, in the books he has written and is writing. Prof. Partington's interest in the history and literature of science, based largely on his own extensive library, is apparent in all his works, and as an authority in this field he is president of the British History of Science Society and a member of the committee of the London Library. Since he intends to continue writing, chemists generally will be happy to know that they are likely for many years to come to have the benefit of his encyclopædic knowledge presented to them with the meticulous clarity and precision they have learned to expect from him.

Dr. M. J. S. Dewar

DR. M. J. S. DEWAR, who succeeds Prof. Partington at Queen Mary College, was educated at Winchester and Balliol College, Oxford. For the past six years he has been working at Messrs. Courtaulds Research Laboratories at Maidenhead. Dr. Dewar has become prominent mainly for his theoretical work in applying wave mechanics to problems of organic chemistry, though in recent years he has also made interesting kinetic studies of polymerization and oxidation processes. His book on "The Electronic Theory of Organic Chemistry" has been one of the most stimulating and controversial contributions to organic chemistry of recent years. In it he has elaborated applications of the wave concept of the probable behaviour of the reactive 'π-electrons' of unsaturated and aromatic systems in the interpretation of the mechanisms of organic reactions, and has shown how these theories can be extended in consideration of the transition states of reacting systems. Undoubtedly the most notable advance in organic chemistry which has resulted from these concepts is the recognition of the aromatic character of the seven-membered ring in tropolone, and of its existence in several natural products, as, for example, colchicine. As yet, few accurate experimental results are available for testing the more quantitative implications of Dr. Dewar's many computations, but it now appears that the modern analytical techniques of isotope analysis and infra-red spectroscopy should facilitate the rapid growth of the more quantitative aspects of organic chemistry to which wave mechanics will provide an essential theoretical background.

Industrial Research in East Africa : Mr. H. B. Stent

MR. H. B. STENT has been appointed director of industrial research in East Africa. This step results from discussion between the East Africa High Commission and the Standing Committee on Finance of the Central Legislative Assembly on ways of speeding up the establishment of an industrial and research organization to provide adequate scientific background for the existing industries in East Africa and to encourage new industrial development. It had first been envisaged that an organization should be established with functions similar to those carried out by the Department of Scientific and Industrial Research in Great Britain. Detailed consideration indicated, however, that it would be more effective to set up an organization mainly confined to matters having a high priority in relation to development in East Africa. Mr. Stent has acted as chairman of the East African Research Board since 1946.

It has also been agreed by the Governments of the three High Commission territories that the present Industrial Research Board should be reconstituted as a Scientific and Advisory Committee under the chairmanship of the director. It will consist of scientific and technical representatives of the three territories, together with a panel (also nominated by them) of persons specially qualified in particular branches of science and technical matters. This new Committee will be advisory to a new and smaller Board comprising representatives of the High Commission and the three territories, which will be under the chairmanship of the Administrator to the High Commission. The new Board's duties will be, principally, the maintenance of full liaison between the organization and the Governments, determination, with the consent and backing of Governments, of priorities, etc., affecting research, and the review of progress in research. It is expected that the new Board will be constituted shortly. The laboratories operating under the old Industrial Research Board have, during the past few years, carried out research into a large number of matters concerning industrial development in East Africa, in addition to analytical work. These matters include investigations on phosphatic fertilizer production; refractories and ceramics, including bricks and roofing tiles and drain pipes as well as domestic pottery; cement production; charcoal production with by-products; soda production from Lake Nakuru; and the extraction and treatment of fresh pyrethrum flowers.

Statistics at the Australian National University, Canberra: Prof. P. A. P. Moran

A CHAIR of statistics has recently been created in the Research School of Social Sciences in the Australian National University, Canberra, and Dr. P. A. P. Moran has been elected as its first occupant. Dr. Moran, who is thirty-four, was born in Sydney and educated at St. Stanislaus' College, Bathurst, at the University of Sydney, and at St. John's College, Cambridge. During the Second World War, he served as an experimental officer in the Ministry of Supply and (later) as Australian scientific liaison officer for physics and operational research. Since the War, he has been lecturer in mathematics at Trinity College, Oxford, University lecturer in mathematics, and a senior member of the Oxford Institute of Statistics. He is a Fellow of the Royal Statistical Society and has played a prominent part in the post-war development of the Society's Research Section, and in the creation of a school of mathematical statistics in Oxford. Apart from earlier work on the pure mathematics of measure, Dr. Moran is chiefly known for his papers on the statistical theory of ranking, and on the theory of stationary time-series. He has collaborated with Prof. A. S. C. Ross on the dating of manuscripts by the statistical analysis of philological data, and with the Oxford Bureau of Animal Population on some problems of population dynamics. At the present he is interested in the problems of estimation arising out of the theory of stochastic processes.

American Scientific Mission to West Germany

AN American scientific mission, headed by Dr. Harold Vagtborg, president of the Southwest Research Institute, San Antonio, Texas, is undertaking a survey of West Germany's scientific research resources under the sponsorship of the Economic Co-operation Administration. In addition to staff members from the Southwest Research Institute, the group, which is spending a month in Europe with headquarters at Bonn and Paris, includes research officers from the Armour Research Foundation of Chicago, the Battelle Memorial Institute of Columbus, and the Stanford Research Institute of Palo Alto. The primary object is to determine whether a need exists for the establishment of applied research institutes to serve small and medium-sized manufacturers and processors in West Germany in the interest of national security and, if it does, how best to set up such laboratories. The West German Government itself asked for this survey to be made. The same group has already given assistance in establishing similar industrial research laboratories in Norway, and in the development of a programme leading to the inauguration of a scientific institute in Brazil. It is hoped to carry out similar surveys in other countries of Western Europe.

Advisory Committee on Metals Economy

THE Minister of Supply, in conjunction with the Lord Privy Seal as Minister of Materials, has appointed an Advisory Committee on Metals Economy to help him to ensure the most economical use of metals in the engineering industry and in the defence programme. The terms of reference of the committee are: "To bring under review in consultation with the various Government and industrial authorities concerned ways of economizing in the use of scarce metals in the design, specification, and the manufacturing process of metal goods for both rearmament and civil purposes, and to advise the Government how it can best assist in promoting such developments".

The committee will be under the chairmanship of Mr. D. A. Oliver, director of research at the Birmingham Small Arms Co., Ltd. The other members are drawn from industry and Government departments. The industrial members are: Dr. G. L. Bailey, British Non-Ferrous Metals Research Association; Mr. H. A. R. Binney, British Standards Institution; Mr. H. H. Burton, English Steel Corporation, Ltd.; Mr. W. C. F. Hessenberg, British Iron and Steel Research Association; Mr. E. W. Grinham, Standard Motor Company, Ltd.; Dr. Ivor Jenkins, General Electric Co., Ltd.; Dr. L. B. Pfeil, Mond Nickel Co., Ltd.; and Dr. C. J. Smithells, British Aluminium Co., Ltd. The secretary is Mr. K. M. McLeod, of the Engineering Industries Division of the Ministry of Supply.

Student Health Services

THE sixteenth issue of *Communication*, the organ of the International Association of University Professors and Lecturers, contains the Association's report upon the provision made in the universities of many countries for the health of their students. Some time ago a questionnaire was addressed to university authorities in all countries, thirty-six of which replied. In these thirty-six countries the great majority of universities accept the principle that they have some responsibility for the health of their students as well as for the way in which services should be organized and paid for. From the replies received it is clear that in the health examinations of the ordinary student at entrance to the university and on subsequent occasions very real importance is attached to the X-ray examination of the lungs. There is a general consensus of opinion that there should not be any exacting psychological examination of the ordinary student's mental health, although in some cases the help of a psychiatrist has been sought. The Association recommends that, in assessing the menta health of a student, the indirect approach is the most suitable, although a counselling psychological service is advised for the universities of countries which have suffered most from the War. The report also contains sections setting out the Association's views on the provision of some form of health instruction, the inspection of the student's environment, the treatment of minor ailments of the sick student and the treatment of students who are seriously ill.

Pests of Ornamental Plants

The late G. Fox Wilson performed a great service to horticulture in his studies of insect and other pests which attack flowers and shrubs, and a compendium of these studies was first published by the Ministry of Agriculture and Fisheries in 1937. This has long been out of print, so that a second edition, enlarged and modernized, is very welcome (Bulletin No. 97, Pests of Flowers and Shrubs; 105 pp.+117 pl.; London: H.M. Stationery Office, 1950; 4*s*. 6*d*. net). A short general introduction is followed by fairly detailed consideration of measures of control. The more ubiquitous pests such as slugs, millepedes, aphids, wireworms and leatherjackets are described in a general section, and thereafter localized pests on lawns, borders, bulbs and corms, rock gardens and glasshouses receive consideration. Such a horticultural arrangement necessitates a more adequate index than is provided, for it is not always easy to make rapid reference to a particular pest. This slight criticism must not, however, be allowed to detract from the value of the bulletin, which is a sound book of reference, thoroughly informative and very well illustrated. It should appeal to the gardener and equally to the advisory officer. One useful feature is that the results of future work with modern sprays, like HETP and TEPP, or modern soil treatments like benzene hexachloride, will be readily applicable to the text, for control measures have been considered as principles rather than mere specific remedies.

St. Andrews Mathematical Colloquium, 1951

Many mathematicians will remember with pleasure the colloquia held at the University of St. Andrews under the sponsorship of the Edinburgh Mathematical Society in 1926, 1930, 1934 and 1938. It was intended to hold such meetings every four years, but the War and the difficult post-war conditions made this impossible until now. The fifth St. Andrews Colloquium took place during July 18–28, and proved even more successful than its predecessors. There were 110 people present at University Hall, St. Andrews, including overseas representatives from Australia, Belgium, Canada, Egypt, Eire, Holland, India, Switzerland and the United States. The inaugural address was given by Prof. H. W. Turnbull, who gave an account of the fascinating historical researches arising from the preparation for publication by the Royal Society of the letters of Isaac Newton. There were five sets of formal lectures: (1) Prof. H. S. M. Coxeter (Toronto) on kaleidoscopes and quadratic forms; (2) Prof. A. Erdélyi (Pasadena, California) on the analytic theory of systems of partial differential equations; (3) Mr. A. E. Ingham (Cambridge) on the analytic theory of numbers; (4) Prof. J. L. Synge (Dublin) on the geometry of function-space and its applications to mathematical physics; (5) Prof. G. Temple (London) on mathematical problems of supersonic aerodynamics. In addition, single lectures were given by Prof. Sophie Piccard (Neuchâtel) on the theory of groups and by Prof. L. E. J. Brouwer (Amsterdam) on the influence of mathematics on logic. At the concluding meeting, Prof. Temple expressed the thanks of all present to those responsible for the successful organization of the colloquium, in particular to Dr. D. E. Rutherford (St. Andrews). It is hoped that the sixth St. Andrews Colloquium will be held during 1955.

Society of Dairy Technology

The Council of the Society of Dairy Technology has established a medal, to be known as the Society of Dairy Technology Gold Medal, which will be awarded to anyone from any part of the world who, in the view of the Council, has rendered particularly distinguished service to the industry. The award will be made not more than three times in ten years. The first award, to be presented at the Society's annual general meeting in London on October 22, is being made to Dr. Richard Seligman, who has been responsible for many developments of outstanding and world-wide importance in the dairy industry.

The Council of the Society has elected Mr. James Mackintosh, lately principal livestock husbandry officer, South-Eastern Provinces, National Agricultural Advisory Service, and formerly head of the Dairy Husbandry Department of the National Institute for Research in Dairying, and Mr. E. B. Anderson, lately chief chemist of United Dairies, Ltd., to be honorary members of the Society of Dairy Technology, in recognition of their services to the dairy industry and to the Society.

Announcements

Applications are invited for the Gabriella Zuccar research grant of 250,000 lire for work at the Zoological Station of Naples for at least six months during 1952. The grant may be renewed for a maximum of three years. Applications, including an outline of the proposed investigation, should reach the Rector, University of Padua, by October 31.

The twenty-sixth annual conference of Aslib will be held at Ashorne Hill, near Leamington Spa, during October 5–8. The programme will include such subjects as the training and organization of staff, including voluntary workers and students; what can be learnt from industrial efficiency methods, such as job analysis, time and motion study, etc.; and practical bibliographical and documentary projects in operation in the international field, with special reference to the part of Unesco in them. Opportunities will be provided for groups to discuss subjects in their particular field of interest. Further details can be obtained from Aslib at 4 Palace Gate, London, W.8.

The United Nations Department of Public Information has now issued a 36-page pamphlet, "World Facts and Figures" (New York: United Nations; London: H.M. Stationery Office, 1951. 25 cents; 1*s*. 9*d*.), giving some cogent facts about population, production, including coal and petroleum, electrical energy, steel, strategic metals, cement, rubber, sulphuric acid, transport and communications, medical facilities and newspapers. These are taken from second editions of the "United Nations Statistical Year Book" and "Demographic Yearbook". The facts included are sufficiently comprehensive for the pamphlet to provide the ordinary man or woman with a convenient means of keeping some current discussions on a factual basis.

EGG-SHELL FORMATION IN TREMATODES AND CESTODES AS DEMONSTRATED BY THE METHYL OR MALACHITE GREEN TECHNIQUES

By Dr. J. D. SMYTH
Department of Zoology, Trinity College, Dublin

DURING recent work on cestode physiology, it was observed that two chemically related dyes —methyl green and malachite green—showed a very marked affinity for the material which formed the egg-shell in certain Diphyllobothriidae. Further observations revealed that the egg-shell in trematodes possessed a similar affinity.

The essentials of the method, which have been published in detail elsewhere[1], involve fixation of worms in 5 per cent formol-saline and staining of sections in 0·5 per cent aqueous methyl or malachite green, combined with a red nuclear counterstain where necessary. It is stressed that these stains are made up in pure aqueous solution, free from acetic acid—the latter converting them into precise nuclear stains, in which form they are usually used in animal cytology.

These stains have been found to be absolutely specific for shell material, and stain it a brilliant green (malachite green) or greenish-blue (methyl green). Thus, any gland, tube or duct containing shell material may be readily identified in sections.

The method greatly simplifies investigation of the mechanism of egg-shell formation in these groups, as the egg-shell material may be traced from its origin to its final moulding into a typical shaped egg in the lower part of the uterus.

Egg-shell formation in Trematodes. It has long been realized that in trematodes the shell material is produced not in the 'shell' gland (Mehlis's gland), but in the so-called 'vitelline' glands ('vitellaria'). The evidence for this view has been ably summarized by Stephenson[2], who has also shown that the egg-shell material is an ortho-dihydroxyphenol-protein complex. The function of the Mehlis gland remains obscure and a number of views have been put forward; the most recent—that of Stephenson[2]—suggests that the main function of the gland is to produce a fluid which increases spermatozoan activity.

Application of the methyl or malachite green techniques confirms and demonstrates clearly the origin of the shell material in cells of the 'vitelline' glands, as spherical globules (*S*, Fig. 3) which stain specifically and intensely in these stains. Not all the cells produce shell at the same time, but in each acini inactive cells free from shell occur (*I*, Fig. 3). Due to the presence of the shell globules in the 'vitelline' glands, these glands stand out clearly in sections from the surrounding tissue (*VG*, Fig. 1). The 'vitelline' cells, loaded with shell globules, may easily be traced along the 'vitelline' ducts and into the lower uterus where, on meeting the ova, they release the contained shell globules, which fuse, to become moulded into typical shaped eggs.

Egg-shell formation in Cestodes. The pseudophyllidean cestodes are characterized by possessing shelled eggs similar to those of digenetic trematodes and, also, numerous 'vitelline' glands. The general arrangement of both male and female genitalia also closely resembles that of digenetic trematodes. It might be speculated, therefore, that the eggs in this group of cestodes would be formed in a manner similar to that in the trematodes. Due, no doubt, to the fact that the genitalia in cestodes are smaller and more compressed—being confined to the limits of a proglottid, whereas a fluke of much larger size contains only one set of genitalia—the mechanism of egg-shell formation in this group of cestodes has never been worked out.

Nevertheless, evidence from recent physiological work has strongly suggested that the egg-shell in pseudophyllidean cestodes originates in the 'vitelline' glands. Thus, when such worms are removed from the host gut, they appear colourless; but on exposure to air, the eggs darken rapidly (as in trematodes) and the 'vitelline' glands likewise take on a brown colour. Again, when the pseudophyllidean cestode, *Schistocephalus solidus*, is cultured to maturity *in vitro* under aerobic conditions (that is, with a stream of air passing through the culture medium), the 'vitelline' glands darken rapidly as maturation approaches and only a few shell-less or very abnormal eggs are produced[3,4]. Such phenomena could be

Fig. 3. 'Vitelline' cells of *Fasciola* in 'vitelline' glands (malachite green)
Fig. 4. 'Vitelline' reservoir and duct of *Schistocephalus* (methyl green). All material fixed formol-saline. *G*, gut; *I*, inactive cell; *N*, nucleus; *S*, shell globules; *SB*, shell blebs; *Y*, yolk; other letters as in Fig. 5

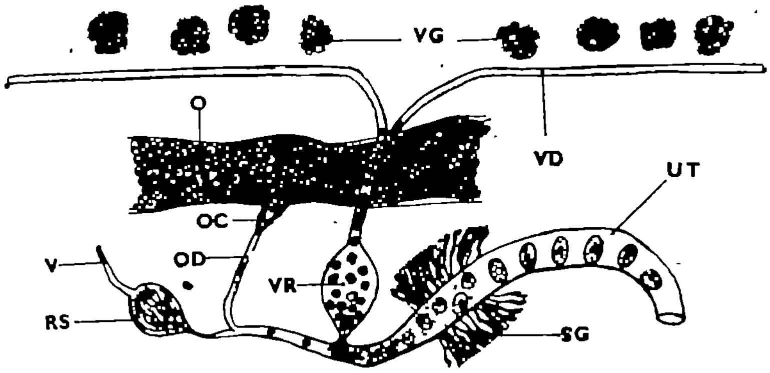

Fig. 5. Diagram of female genitalia in proglottid of *Schistocephalus* to illustrate method of egg-shell formation. *O*, ovary; *OC*, oöcapt; *OD*, oviduct; *RS*, receptaculum seminis; *SG*, 'shell' gland (Mehlis's gland); *UT*, uterus; *V*, vagina; *VD*, 'vitelline' ducts; *VG*, 'vitelline' glands; *VR*, 'vitelline' reservoir

explained by the supposition that the shell material is being produced in the 'vitelline' glands; but due to the high oxygen tension it becomes prematurely tanned and hardened so that the shell globules are unable to fuse together to form proper shaped egg-shells. Although such experimental evidence was highly suggestive, it was not previously possible to confirm such speculations by histological methods.

Application of the methyl and malachite green techniques has enabled the egg-shell formation in three members of the Diphyllobothriidæ—*Schistocephalus solidus*, *Ligula intestinalis and Diphyllobothrium* sp.—to be demonstrated histologically with little difficulty.

After staining, the presence of large, bright green globules in the cells of the 'vitelline' glands may be immediately recognized. As these cells pass down the 'vitelline' ducts (*VD*, Figs. 4 and 5) through the 'vitelline' reservoir (*VR*, Figs. 4 and 5) and into the lower uterus, they release the contained shell globules which here fuse together to form the typical oval egg-shell which encloses a fertilized ovum and some 'yolk' (the remains of the 'vitelline' cells which now only contain nuclei and small pink-staining granules). The 'vitelline' glands thus provide both shell and yolk material to the fertilized ovum. In *Ligula*, the process of egg-shell formation is identical with that in *Schistocephalus*. In *Diphyllobothrium*, the shell globules fuse to form larger globules (*SB*, Fig. 2) before finally forming a moulded egg-shell, and these large globules stand out clearly from the yolk in the lower uterus. It may be remarked that I had been attempting to work out the mode of egg-shell formation in the *Diphyllobothriidæ* for the past five years without success. From sections stained in methyl green, it was possible to trace out the entire process in a matter of a few hours.

Position of cyclophyllidean cestodes. The cyclophyllidean cestodes differ from the pseudophyllidean cestodes in that their eggs lack an external egg-shell —the so-called 'egg-shell' being, in fact, merely a thickened embryophore. This lack of an external egg-shell is clearly correlated with the absence of a free-swimming larval stage—such as occurs in the pseudophyllidean cestodes and trematodes—from the cyclophyllidean life-cycle.

On theoretical grounds, therefore, it was speculated that the 'vitelline' glands in cyclophyllidean cestodes would be free from globules of shell material and concerned only with the production of yolk material. Investigation of the histology of the 'vitelline' glands of *Tænia saginata* by the methyl green technique has confirmed this hypothesis—the 'vitelline' cells being quite free from shell material and acting as yolk producers only.

There is thus a marked distinction between the 'vitelline' glands of these two groups of cestodes—one type producing yolk alone, the other both shell and yolk. To retain the term 'vitelline' glands for both only introduces confusion. With the present terminology, students are informed that the 'vitelline' glands produce shell, and the 'shell' gland does not—an unfortunate and confusing state of affairs. In order to clarify this position, it is proposed that the use of the term 'vitelline glands' or 'vitellaria' should be restricted to glands that produce only yolk (that is, in the Cyclophyllidea). For glands that produce both yolk and shell (that is, in the trematodes and pseudophyllidean cestodes) it is suggested that a new term—*vitellocalycal* glands—be introduced. The term 'shell gland' should be dropped entirely and replaced by 'Mehlis's' gland—as, indeed, is the increasing tendency in recent text-books of helminthology—until its function has been established.

I am indebted to the Medical Research Council of Ireland for financial assistance towards the expenses of this work. [April 2.

EFFECTS OF A PROTEIN-FREE DIET ON THE ALKALINE AND ACID PHOSPHATASE ACTIVITY OF THE LIVER OF THE RAT

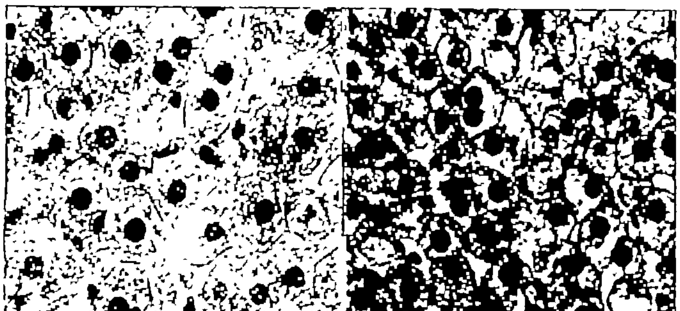
By J. O. ELY and M. H. ROSS

Biochemical Research Foundation, Newark, Delaware

PROTEINS, phospholipids and ribonucleic acids are lost rapidly from the livers when rats are fasted[1,2] or fed a protein-free diet[3]. It was suggested by Perlmann and Ferry[4] that acid phosphatase is a water-soluble protein, and alkaline phosphatase is a water-insoluble, salt-soluble globulin. Loss of protein from the liver because of a restricted dietary protein intake from any cause might alter the phosphatase activity. If this be true, any experiments on the effects of various agents on phosphatase activity should take into consideration the effect of the experimental regime on the food intake of the animals.

The effects of a protein-free diet, in contrast to an adequate diet, on the alkaline and acid phosphatase activity of the liver of rats have been investigated by chemical and by cytochemical methods.

Experimental. Male rats of the Wistar strain, 150 gm. initial weight, were maintained on (1) a protein-free diet (dextrose, 89 gm.; corn oil, 5·0 gm.; salt mixture, 4·0 gm.; rice bran extract ('Vitab'), 2·0 gm.; riboflavin, 0·2 mgm.) and (2) Fox Food Blox diet (Allied Mills). At intervals of from five to forty-nine days, rats from each group were de-



Phosphatase activity in sections of livers of rats. The photographs for each phosphatase were prepared under identical treatment, exposure and development time. Magnification × 580. (*a*) Alkaline phosphatase activity in section from liver of rat fed Fox Food Blox diet for 49 days. (*b*) Alkaline phosphatase activity in section from liver of rat fed protein-free diet for 49 days. (*c*) Acid phosphatase activity in section from liver of rat fed Fox Food Blox diet for 49 days. (*d*) Acid phosphatase activity in section from liver of rat fed protein-free diet for 49 days

capitated, and samples of liver weighing 0·1–0·2 gm. were removed and were ground with sand and distilled water. After standing for 30 min. at 15° C. in 5 c.c. of distilled water the suspension was filtered through No. 1 Whatman filter paper; the filtrate was used for the chemical estimation of phosphatase. Chemical determinations of alkaline phosphatase activity were made by the method of King and Armstrong[5] and of acid phosphatase activity by the method of King and Armstrong as modified by Gutman and Gutman[6].

Cytochemical determinations of alkaline and acid phosphatase activity were made by the methods of Gomori[7,8]. For alkaline phosphatase activity determinations thin pieces of liver from the rats of each dietary group were treated alike during the process of fixation (80 per cent ethyl alcohol) and dehydration. For acid phosphatase activity determinations the tissues were fixed in acetone for two hours, and were then dehydrated and embedded in paraffin; the whole process was completed in seven hours. A specimen from each dietary group was embedded in the same block of medium so that sections to be compared were cut at the same stroke of the microtome knife and were mounted on the same microscopic slide.

Results. The filtrates prepared from the livers of rats fed the protein-free diet exhibited per unit of nitrogen approximately twice as much alkaline phosphatase activity, and approximately the same acid phosphatase activity as did the filtrates prepared from the livers of the rats fed the Fox Food Blox diet (see accompanying table).

The cytochemical demonstration of phosphatase activity in microscopic sections of tissue showed that the alkaline phosphatase activity was much greater in both nuclei and cytoplasm of the livers of the rats fed the protein-free diet than in the livers of the rats fed the Fox Food Blox diet (Figs. *a* and *b*). Acid phosphatase activity, however, was much less in the nuclei and cytoplasm of the livers of the protein-free diet fed rats than in the livers of the rats fed the Fox Food Blox diet (Figs. *c* and *d*). The photographs show also that the nuclei are more numerous in equal areas of the sections, and, therefore, in equal volumes of tissue, from the livers of the rats fed the protein-free diet than from the livers of the rats fed the Fox Food Blox diet.

Discussion. The results of the chemical and cytochemical estimations of alkaline phosphatase activity are in agreement; that is, both methods showed greater enzyme activity in the livers of the rats fed the protein free diet. The results of the acid phosphatase determinations are not in agreement; cytochemically, there was less acid phosphatase activity in the sections from the livers of the rats fed the protein-free diet and no significant difference in the activities per unit of nitrogen in the filtrates. It appears, therefore, that in the filtrates from the livers of the rats fed the protein-free diet a greater amount of enzyme was associated with a unit amount of nitrogen than in the filtrates from the livers of the rats fed the Fox Food Blox diet. This, it seems, indicates that during protein depletion rat liver loses less non-enzyme nitrogen than enzyme nitrogen (acid phosphatase).

It is of interest that the alkaline phosphatase activity in the nuclei of the livers of the rats fed the protein-free diet was greater than in the nuclei of the livers of rats fed the Fox Food Blox. It was shown recently[9] that under similar conditions the feeding of a protein-free diet was followed by an increase in the deoxyribonucleic acid content of the nuclei of rat livers. Brachet and Jeener[10] and Brachet[11] state that a direct parallel exists between

PHOSPHATASE ACTIVITY OF EXTRACTS OF LIVERS OF RATS FED DIFFERENT DIETS

the rate of turnover of the phosphate in deoxyribonucleic acid and the amount of alkaline phosphatase of the nuclei. The experiments reported here seem to indicate a parallelism between the alkaline phosphatase activity and deoxyribonucleic acid content in nuclei of rat-liver; the rate of phosphorus turnover, however, is not known.

The changes in phosphatase activity found in these experiments apparently are much greater than those previously reported for rat livers. Wachstein[12] found a slight decrease in acid phosphatase activity during protein depletion, and a moderate increase in alkaline phosphatase after 6–18 days on a protein-free diet.

Both the alkaline and acid phosphatase contents of the liver appear to be significantly influenced by protein intake. It would seem important to take this fact into consideration in both the planning and the interpretation of experimental work.

Summary. Alkaline phosphatase has been shown chemically and cytochemically to be increased in both nucleus and cytoplasm during protein depletion produced in rats by the feeding of a protein-free diet. Acid phosphatase, on the other hand, has been shown cytochemically to be reduced in both nucleus and cytoplasm. Other proteins of the liver are apparently reduced to a greater extent than acid phosphatase.

OPTICAL ROTATION AND CHAIN FOLDING IN SYNTHETIC POLYPEPTIDES AND GELATIN

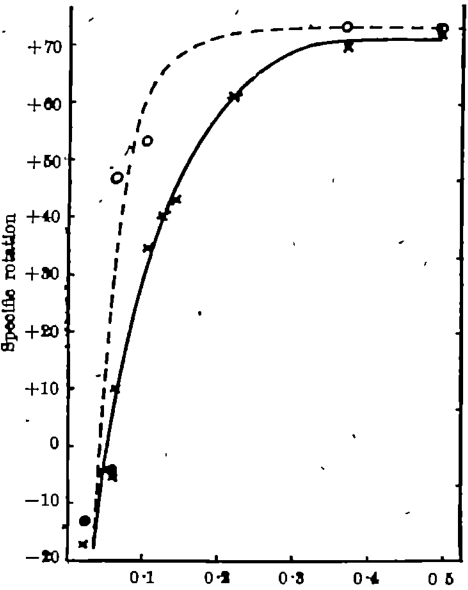
By Dr. CONMAR ROBINSON and M. J. BOTT
Research Laboratory, Courtaulds, Ltd., Maidenhead

IN a chain of atoms containing asymmetric carbon atoms, movements of groups of atoms in the chain relative to those asymmetric carbon atoms would be expected to affect the magnitude and even the sign of the optical rotatory power. Further, if such movements involved in a change of configuration result in ring formation, the consequent reduction of free rotation may also be expected to increase greatly the optical rotation. Recent work in this Laboratory has indicated that the 'α-keratin' configuration of the polypeptide chain is produced by folding the extended β-form into seven-membered rings, held together by intra-chain hydrogen bonds[1,2]. It follows that the $\alpha \rightleftarrows \beta$ transformation would be expected to be accompanied by a change in the specific rotation.

We have recently made some experiments with a synthetic polypeptide (γ-methyl-L-glutamate D-L phenylalanine copolymer). If the molecular weight is not too low, films prepared by evaporating *m*-cresol solutions of this polymer are found to be in the α-form; but as the molecular weight is decreased, there is an increasing tendency to form the β-configuration (compare the similar tendency found for small polypeptides by Bamford, Hanby and Happey[3]). Samples having different molecular weights were prepared and their specific rotations in *meta*-cresol were measured. A rough estimate of the percentage α-fold in the films obtained by evaporation of the solutions was obtained by making use of the fact that the CO-stretching frequency has a characteristic value for both the α- and β-configurations. The results, together with the specific viscosities of the 1 per cent solutions, are shown in the accompanying figure. It will be seen that there is a striking relationship between the specific rotation of the solutions and the percentage of the α-configuration in the films prepared from them. That the differences in specific rotation are not a *direct* effect of molecular weight can be seen by examining solutions of the same polypeptides in formic acid. Here the specific rotations fall between −14° and −18° for the whole range of molecular weights, while the films prepared from these formic acid solutions all show between 60 and 75 per cent of the β-fold. It seems, therefore, reasonable to assume that the changes in specific rotation in *meta*-cresol solutions are largely determined by changes in the proportions of the α- and β-configuration.

The results suggested that it would be possible to use the optical rotatory power as an indication of the change of configuration in protein solutions. Some interesting results have been obtained with gelatin. As is well known, on cooling a gelatin solution from above 35° C. to room temperature, the specific rotation approximately doubles in value. This mutarotation is closely connected with the gelling properties, and it has been suggested more than once that there are two forms of gelatin, one stable above approximately 35° C. and one which is only found below this temperature. Collagen, and gelatin in a film obtained by cold evaporation, have a characteristic configuration which is neither the α- nor the β-fold. This is shown not only by the X-ray diagrams but also by polarized infra-red absorption by oriented specimens. Ambrose and Elliott have proposed a configuration which is in conformity with these data, in which the fold is held together by *inter*-chain hydrogen bonds[4]. The collagen fold has a characteristically high N—H stretching frequency of 3,330 cm.$^{-1}$ as compared to 3,305–3,310 cm.$^{-1}$ for the α- and β-folds in other proteins, and this may be used to identify it in unoriented specimens.

Two 5 per cent solutions of gelatin (*p*H 6·8) were prepared and kept at room temperature and 40° C. respectively. After three days the specific rotation of the cold solution had become almost steady at −262°. The hot solution, which reaches equilibrium rapidly, had a specific rotation of −128°. The specific rotation of a film prepared by evaporation of the hot solution had almost the same value as the hot solution and did not change within twenty-four hours after cooling. On the other hand, a film prepared from the cold solution by evaporation at room temperature showed a rotation (*c*. −1,000°) which was very much higher than that of the corresponding cold solution. These results indicate that we have succeeded in obtaining the hot form of the gelatin in a 'frozen' state which was suitable for studying at room temperature. The N—H stretching frequencies of the



× - - -, specific rotation ; ○ - - -, per cent α-fold

hot and cold evaporated films were found to be at 3,310 cm.$^{-1}$ and 3,330 cm.$^{-1}$ respectively.

These values suggest that the collagen fold is not present in the hot evaporated film; but unfortunately the data do not allow us to decide whether this film is in the α- or the β-configuration. The results, however, allow us to put forward a tentative picture of the gelling mechanism. Above 35° C. gelatin would appear to exist in a form which does not allow hydrogen bonds to exist between the molecules. This condition would be satisfied either by the α-fold or by a β-fold preferentially forming hydrogen bonds with the water. On concentrating such a hot solution there is little change in the optical rotation, which strongly suggests that it is in the α- rather than in the β-configuration. Below 35° C. the existence of the collagen fold becomes possible where lengths of parallel chain come into contact; a three-dimensional network is built up consisting of lengths of single molecules joined together by small regions of parallel chains in the collagen configuration (the presence of more than 20 per cent proline and hydroxy-proline means, however, that there will be many residues which cannot be hydrogen-bonded in the α-fold). Where the concentration and number of collagen folds cross-linked are sufficiently high, the network will permeate the whole solution, which will then set to a gel. On ageing, the organized regions in the collagen fold increase; this will continue until steric restrictions prevent the further growth of the organized regions. The ageing is accompanied by an increase in specific rotation and rigidity. On concentrating the gel there is a further large increase in the proportion of collagen fold, as indicated by the further marked increase in the optical rotation.

In attributing the origin of the gel formation to the formation of the collagen fold, we are assuming that any contribution from side-chain interaction will be of secondary importance. This is in accordance with the observation that the optical rotation[5] as well as the melting point[6] and rigidity[7] of the gel are little dependent on pH.

If increasing quantities of certain salts (for example, lithium bromide, iodide or thiocyanate) are added to a cold gelatin solution, the specific rotation falls to a limiting value which is very near that for the hot solution, while at the same time gel formation is prevented[8]. It would seem that high concentrations of such salts convert cold gelatin from the inter-chain-hydrogen-bonded form to the intra-chain-hydrogen-bonded α-form. It is significant that lithium bromide, as Ambrose, Bamford, Elliott and Hanby[9] have shown, converts silk from the inter-chain-hydrogen-bonded β-form to the water-soluble α-form.

Our thanks are due to Mr. E. J. Ambrose for having first directed our attention to the fact that a correlation between optical rotation and the chain configuration in polypeptides was to be expected from theories of optical rotatory power, to Dr. A. Elliott for obtaining the infra-red radiation data on gelatin, and to Mr. N. B. Abbott for that on polypeptides. We also wish to thank Mr. W. E. Hanby for preparing the range of polypeptide specimens.

A HUNDRED YEARS OF ORGANIC CHEMISTRY (1851–1951)*

THE century 1851–1951 has been an eventful one for organic chemistry. Indeed, it has seen the science grow from a rather confusing and empirical body of facts into one of the most systematic and fascinating of the sciences, and one on the progress of which many of the amenities of our modern civilization depend.

1851 might almost be regarded as a turning point in organic chemistry, for major developments destined to shape the whole course of the science were at hand. It will be recalled that early in the nineteenth century Berzelius had defined organic chemistry as the chemistry of substances produced by living matter, in contradistinction to the inorganic substances of mineral origin. There were certain striking differences between the two types, and in Berzelius's mind, as in those of his contemporaries, these were associated with the vital force concept. Wöhler's laboratory synthesis of urea in 1828 is generally believed to have sounded the death knell of the vital force theory; but, in fact, it survived for long after that and it still rears its head in the famous text-book of Gmelin (1854). In the years that followed Wöhler's discovery, however, Liebig and others had shown that the organic compounds all contained carbon and that carbon compounds with similar properties could be obtained from non-living sources, for example, coal tar. So it gradually came to be recognized that organic chemistry was, in effect, synonymous with the chemistry of the carbon compounds, and attention was directed to the understanding of carbon chemistry, since it was clear that

* Substance of a paper read by Prof. A. R. Todd, F.R.S., before Section B (Chemistry) of the British Association on August 9.

until such an understanding was obtained little progress was to be expected in studying the chemistry of living matter.

By 1851 the efforts of many chemists had produced a substantial body of factual knowledge ; but despite type theories and radical theories, there was no really satisfactory theory of valency which could correlate the facts and establish the interrelationships of organic compounds. In 1852 E. Frankland made the first clear statement of the idea of valency or fixed combining power of an element. This was a great step forward, and it was followed in 1858 by the work of Kekulé and Couper, who independently put forward a theory of molecular structure based on the quadrivalency of carbon and the capacity of carbon atoms for joining together in chains ; they showed how molecular constitution could be represented diagrammatically in graphic formulæ and could predict the existence of isomers. That more isomers did, in fact, exist than were allowed for by this theory was, however, clear from the earlier work of Pasteur, who had shown that two optically active tartaric acids exist. This was clarified in 1874 by van 't Hoff and Le Bel, who added to the Kekulé–Couper ideas the concept of the tetrahedral carbon atom and thereby introduced the idea of space- or stereo-isomerism. With this the whole subject was placed on a firm basis, and on these theories virtually the whole of the modern science arose. Only in comparatively recent years have alterations in basic ideas of molecular structure come from physics through knowledge of the electronic structures of atoms, but even these new ideas have not altered the essential applicability of theory laid down between 1850 and 1874.

Armed with this understanding of structure, the study of the carbon compounds flourished exceedingly, and by the early twentieth century a vast number of such compounds were known and methods of synthesis and analysis had been developed in great variety. During this period, too, began the rise of the great organic chemical industry—producing dyestuffs, starting from the initial aniline dye of Perkin, explosives, etc. This rise of an industry notable for its closeness to the advancing front of a science has continued, until to-day it produces not only dyes and explosives, but also plastics, detergents, photographic materials, drugs, fabrics and a multitude of other things which we accept without question as part of everyday life—there are indeed few of the material comforts of life which do not owe something to organic chemical industry.

The twentieth century has seen, however, a remarkable development in our knowledge of chemistry in relation to living matter. During the latter half of the nineteenth century organic chemists paid scant attention to this side of their subject, and even biochemists—those concerned primarily with the nature of the processes going on in living matter—were relatively few. It is only in this century that great strides in biochemistry have been made.

From the organic chemist's point of view, this was inevitable. The materials found in living matter were too complex for him to study with success until he had mastered the groundwork and developed methods for studying carbon compounds in general. This mastery came from the work of the late nineteenth century, and as the twentieth begins we can see the beginnings of a move towards the goal of the early organic chemists in the work of Fischer, Willstätter and others on the proteins, purines, sugars, natural colouring matters and enzymes. This movement has grown continuously, receiving enormous impetus through the development of microtechniques enabling work to be done with tiny quantities of material ; and in the past twenty-five years it has given most of the spectacular achievement of organic chemistry in the structural elucidation and synthesis of hormones, vitamins, alkaloids, natural colouring matters, etc., and indirectly of the synthetic drugs. Parallel with it have come the developments in the understanding of the finer details of molecular structure and reactivity associated with the names of Lapworth, Robinson, Pauling and Ingold. The welding together of the results and ideas emerging from these two fields of endeavour promise still more striking triumphs for organic chemistry in a future which should be as fascinating as its past.

VERTICAL MIGRATION OF PLANKTON ANIMALS*

MANY of the small plankton animals in the sea which are important as the food of fish such as herring, sprat and mackerel swim upwards towards the surface in the evening and down again to deeper levels after dawn. It is of interest from a purely biological point of view to find out what are the factors which govern these movements, and may also be useful in reaching a better understanding of the shoaling of the herring. The plankton consists of small animals of many different kinds, small jellyfish, worms and molluscs, hosts of small crustaceans and many others ; they nearly all show this nightly vertical migration upwards. Since it has been developed in so many different groups of animals and must use up so much energy every day—some of them climbing more than a hundred feet—it must clearly be of profound significance in their lives. We do not yet understand its meaning and are still only in the stages of studying the actual movements of the animals in relation to different conditions of light, temperature, pressure, etc.

Hitherto it has not been possible to see animals making extensive vertical migrations in the laboratory or to experiment with them while doing so. Now apparatus has been devised which allows this to be done. A curved transparent tube of 'Perspex', of 2 in. by 1¼ in. cross-section, is made to form a complete circle of 4-ft. diameter and is then mounted as a wheel ; a small opening, which may be sealed up, allows it to be filled with water and the experimental animal added. The wheel is now turned so that the animal is half-way up one side ; it can now swim up or down according to the varying conditions of light, etc., which may be controlled ; but as it does so the wheel is turned so that it is actually kept stationary in relation to the observer. It is seen that the animal is swimming in an endless tube ; it can swim up and up, or down and down for hundreds of feet, and the wheel, which is turned all the time, automatically records its speed of swimming on a recording drum. Inside the tube are small doors, some with weights and some with floats, which automatically open and close as the wheel goes round ; they are always wide open at the side at which the animal is swimming and so do not interfere with it, but closed on the other side to ensure that the water turns exactly with the wheel.

---

*Substance of a paper read by Prof. A. C. Hardy, F.R.S., and R. Bainbridge before Section D (Zoology) of the British Association on August 10.

A parallel tube fitted with a photo-electric cell records the light intensity at a point beside where the animal is swimming. The experiments are performed with the wheel in a small glass greenhouse and the intensity of the light varied from bright daylight to complete darkness by a series of white, grey and black screens which can be drawn over the top.

Tracings from the recording drum of the swimming up and down of different animals under different conditions were shown and discussed. *Calanus*, a crustacean, almost the size of a grain of rice and the principal food of the herring, is shown to be able to climb 50 ft. in one hour, and another larger crustacean, *Meganyctiphanes*, almost an inch long, can climb as much as 305 ft. in the same time.

APPLICATIONS OF PLASTICS

AT the British Plastics Convention and Exhibition held in Olympia, London, during June 6–16, the plastics industry was given full opportunity for displaying its products and discussing the technical and practical aspects in the Convention Hall. The industry can claim considerable credit for the display. This relatively new and virile industry is one which uses its chemical raw materials in a careful and efficient manner to produce a very wide range of products and articles which are proving of much benefit to many industries to-day. They enable new assessments to be made of many old problems and processes; new values of durability, resistance to chemical attack or corrosion under atmospheric conditions, beauty and often lower-cost production resulting from their adoption. There is a large range of plastics materials available, and each one of the materials has itself an almost limitless range of applications best suited to its chemical and physical properties. There is in the lighter industries a very considerable scope for their adoption for very many uses.

The various plastics raw materials will be described first, and a few of their chemical and physical properties named. Then some of the outstanding applications for each plastic dealt with in the Exhibition and the Convention will be mentioned. Plastics materials are either moulded or otherwise fabricated into the many articles or other finished products used by the consumer, who may be the public, or the manufacturer of other products used in another industry. It should be stated here that the plastics materials referred to are the organic plastics only, but by common consent in the industry, rubber is excluded from the range.

Celluloid (or Nitrocellulose), discovered in 1865. This is the recognized pioneer material. It is thermoplastic, which means that after it has been shaped while it is hot, it is rigid when cold. But it will soften again on reheating and it can then be reshaped. Although it is the oldest plastic, it still has many uses which would not be improved upon by more modern materials, for example, table tennis balls, covering stretched over metals, such as automobile steering wheels and omnibus rails, hairbrush backs and toothbrush handles, etc. Its inflammability, however, necessitates its use with caution. In its sheet or rod form it is remarkably tough, while, of course, it is unaffected to a large degree by water and many chemicals.

Cellulose Acetate, discovered in 1865. This non-inflammable grade of plastic replaced celluloid for some uses where inflammability was feared. It is a thermoplastic. It came into prominence during the First World War as an aeroplane 'dope'. After that War ended, large stocks were available for utilization, when the process of converting the white powdered cellulose acetate into sheet and rod was developed. A new and relatively safe plastic was available for use in such things as lamp-shades, ornamental articles (for personal decoration, such as brooches, etc.), transparent sheet for packaging, astraldomes for aircraft, fountain-pen barrels, moulding powders, etc.

This material is extremely tough in all its forms and can be made in both rod and sheet form and as moulding material, clear, opaque or translucent (for example, tortoiseshell). Among numerous articles for consumer use made from cellulose acetate are fancy goods, door beading, drawer pulls and handles, spectacle frames, ciné non-flam film, packaging, showcards, protective eyeware.

Cellulose acetate is used to quite a large degree as the raw material for cellulose lacquers, extensively used for general decorative applied finishes. It is also used on ships' fittings, such as covering metal handrails, door furniture, etc.

Casein Plastics, first produced in 1885. This class of plastics is gradually giving way to more modern materials. It is available in sheet or rod form principally, and its present use is mainly for ornamental buttons for the garment industry, which articles are fabricated by machines from rod or sheet. It is not waterproof in the generally accepted sense of the word.

In addition to buttons, many fancy goods are made from it, such as barrels for pencils and fountain-pens, and insulators and articles for resisting low-tension electric currents. Other applications are shoe buckles, knitting pins, umbrella handles, furniture handles, combs, etc., by machining from rod or sheet.

Phenolic Plastics, developed in 1907. This type of plastics is the most extensively used range of materials at present. Phenolic plastics are thermosetting, which means that while hot they may be shaped; but during shaping a chemical reaction takes place which hardens the material in the mould. Further heating does not soften the moulding or shaped piece as in the case of thermoplastic materials. Thus, the finished articles or products made in phenolic plastics may be used for purposes where some resistance to heat is required. Phenolic plastics is only one type of thermosetting material, others being urea-formaldehyde and melamine-formaldehyde plastics (aminoplastics) as described later. The finished articles are extremely hard and, in addition to being resistant to heat, they are also resistant to a wide range of chemicals, but not to alkalis or strong oxidizing agents.

From the resins are made a wide range of products, such as moulding materials, paper and fabric laminated sheets, the more durable types of paints, and varnishes for electrical insulation, units of chemical plant as a structural material, acid-resisting floors, tanks, vats, pipework, etc. Large quantities are used for the manufacture of high-speed grinding wheels, brake and clutch linings for cars, adhesives for plywood manufacture, electric lamp capping cements, metal foundry core binders, etc.

Moulding powders are used to produce large television and radio cabinets in one piece, clock cases, rotary pump impellors, stud-welding pistol grips, car facia boards, Topham spinning boxes and spools for the rayon industry, vacuum cleaner bodies, shop counter drawers, ventilator fan cases and rotors and radio and electrical accessories. In addition, a large range of fancy goods such as cigarette caskets, desk calendars, etc., are produced. The present trend is for larger and larger mouldings to be made.

In its laminated form, using paper or fabric as the interlayer, phenolic plastic is used for plywood facing for furniture, wall panelling for ships and railway carriages, silent gear wheels to transmit both low and high powers, plating barrels, fish plates for railways, stern tubes for the propellor shafts of ships, roller bearings in steel rolling mills, aircraft propellors and structures (for example, the 'Mosquito'), moulded dinghy hulls, etc.

Amino-Plastics—Urea and Melamine, developed in 1920 *and onward.* These are thermosetting. Mouldings with a high degree of beauty can be made, and thus they are used for fancy goods to a large extent. Urea resins are used for plywood adhesives, foundry sand-core binders, surface coatings, treatment of textiles to render them resistant to creasing, increasing the wet strength of papers, permanently stiffened finishes for textiles in admixture with starches or dextrins, controlling shrinkage of fabrics.

Urea and melamine resin mouldings are non-tracking, and thus are widely used for certain electrical insulators where resistance to electrical surface leakage is essential.

Amino materials capable of being made in light colours and delicate pastel shades are used extensively for surface layers of laminated sheet for wall panelling and light-coloured materials for furniture finishing, for example, table and bar counter tops, etc.

Polyvinyl Plastics, developed during 1920–30. These are thermoplastics made as polyvinyl chloride or acetate or copolymers of chloride and acetate. They are also produced as the acetals, butyrals, etc. They are easily worked into sheets and are now extensively used for shower curtains, window furnishings, flooring tiles and raincoats (either as sheet or as coated fabric). They can be made with a high degree of decoration, either clear or opaque and with printed patterns. They are also used for upholstery (leather-cloth), shoe uppers, ladies' handbags, transparent packaging, etc. In the chemical industry, polyvinyl chloride sheet (known as p.v.c.) is used for tank linings, protective clothing, filter cloths. Other applications are: safety glass for motor-car windscreens, yarns for weaving hosiery, fishing nets, etc., 'cocoon' casing for armaments in storage or being shipped to the East. Very large quantities are used for covering electrical cable instead of rubber, and for the manufacture of highly successful primers and other surface coatings.

Polyethylene Plastics, developed 1937–43. They are thermoplastic and possess a very high degree of both chemical and electrical resistance. They are wax-like to the feel and in appearance. They can be used for many items of chemical plant and utensils, such as pipes for conveying many chemicals, and for lining the interior of chemical tanks and vats, containers and utensils for hydrofluoric acid.

The evolution and use of polyethylene contributed substantially to the development of radar during the Second World War, on account of its very low power factor.

It is extensively used as the interior core of undersea cables to reduce electrical losses. It is also used in transparent film form as a packaging material for foodstuffs, drugs (like 'Mepacrin' tablets), flexible bottles by the Plax extrusion blow technique, pharmaceutical tubes, cosmetic containers, etc. Balloons for high-altitude meteorological and other observations can be made of polyethylene. Tubing for cold-water plumbing is also made of polyethylene.

Nylon, developed during 1928–38. This is a polyamide plastic and is a thermoplastic. It is best known for its use in hosiery and specialized garments. Industrial applications include tow ropes for gliders and gear wheels for impellor pumps. As a filler for phenolic moulding materials, it imparts great strength and resistance to alkalis and acids in mouldings. It is used extensively for surgical dressings where 'breathing' outwards only is required.

Methyl Methacrylate, developed in 1938. This is an ethenoid type of plastic and is thermoplastic. Some of its applications are for use in aircraft as radomes from transparent sheet, transparent models or housings for working parts for use in exhibitions, for example, motor-car engines, gear-box casings, etc. It is also used for artificial teeth and dentures, some types of transparent mouldings, camera lenses, spectacle lenses, sculpture or highly ornamental carvings, and rods for transmitting artificial light round bends. It is a material of considerable beauty and consequently is used for a wide range of fancy goods for machining.

Polyethylene Glycol Terephthalate ('Terylene'), developed in 1939 *and onwards.* This is a true synthetic fibre, either silk-like or wool-like in properties. It can be made unshrinkable. It can be easily printed and is probably the most successful synthetic fibre for the textile industry to date. Its tenacity when wet is the same as when dry. It has good drape and handle, and has been used so far for lightweight suits. It is also used for filter cloth and laundry bags, ropes, cord, thread, corset cloth, brassière cloth, industrial overalls and sailcloth. It is expected to follow the pattern laid down by nylon.

The above is a brief outline of the state of the industry up to date; but new products are emerging rapidly and what is new to-day may be old to-morrow.

H. V. POTTER

LIBRARY SERVICE IN GREAT BRITAIN

ANNUAL CONFERENCE OF THE LIBRARY ASSOCIATION

AS one of the means by which scientific and technical knowledge is made more readily available to industry and to the community generally, the public library service must always be of some general interest to the man of science. While his own needs will be met in general by the libraries maintained by his professional institutions, or of the universities, research institutes or industrial organizations or firms with which he is associated, as well as by such national libraries as those of the Patent Office or the Science Museum, they are already to some extent served by the larger public libraries which offer a type of regional service. If the regional libraries or services envisaged by the Panel on Technical Information Services of the Committee on Industrial Productivity ever mature, the public libraries are likely to play an important part in the development.

Little hint of such developments was given at the annual conference held in Edinburgh during June 5–8 by the Library Association; but papers presented at the Conference possess rather more than usual interest for the scientific worker. The presidential address of Mr. James Wilkie, for example, dealt largely with the challenge which the impact of science and technology on everyday life as well as on industry make to the librarian, not only to meet the needs of science and technology but also to assist the citizen to adapt himself to changing conditions. These opportunities of service to all sections of the community were indicated with the vision and sure touch to be expected from the secretary of the Carnegie United Kingdom Trust. The same qualities characterize the general report of the Public Library Inquiry conducted in the United States by the Social Science Research Council, with assistance from the Carnegie Corporation, at a request made by the American Library Association in 1948. The findings of this report were summarized for the Library Association Conference by Mr. W. A. Munford, Cambridge city librarian, and it is clear from his summary that, apart from its bearing on public library service in Great Britain, the report deserves attention in regard to adult education and the extramural work of the universities, at least as indicating some of the questions that should be answered before determining university policy in that field.

Mr. Munford's paper was presented at a session at which the Association looked to its future problems, and another paper contributed to that session, by Miss Gwenda Jones, dealt with the practical issue of the place of reference and technical libraries in the county library system. This is an aspect of the regional problem which has scarcely yet been faced, largely for reasons of space, staff and of money; but it is one which the distribution or dispersal of industry would render ever more important. Decentralization of industry itself explodes the idea that the county library system is a purely rural service completely divorced from industry and science. Miss Jones herself recognizes that the pattern of a county library technical service may be decentralization to the towns where the main industries operate, and that this would necessitate strengthening the branch staffs with technical librarians, possibly joint appointments with that of reference librarian. It is interesting to note also in this paper the suggestion that the county library system should provide employment for more persons with scientific qualifications of the calibre who at present find a place only in the big municipal libraries or the industrial libraries. Doubtless it will not be easy to implement any such suggestion without considerable improvement in the status and salaries which the county library system can offer at present, but the freer movement of men and women both from the public library system into industrial libraries and in the reverse direction is desirable. It could be an important factor in encouraging that mutual understanding of problems and conditions which is a prerequisite in developing the co-operation between libraries to which a whole session of the Conference was devoted.

The paper on reference libraries presented by Mr. Hargreaves, reference librarian of Leeds, at that session, and the papers at the symposium on library service to industry are possibly those of most interest to the scientific worker. Mr. Hargreaves's paper presented a sane and balanced view of the whole problem of inter-library co-operation in which the point of view of the industrial librarian is very fairly reflected. Mr. Hargreaves sees clearly enough the advantages of building up a co-ordinated system, as well as the practical difficulties in doing so, and no one could have indicated more clearly the way in which any such system can be prejudiced or even wrecked by thoughtlessness in the way it is put to use. Some of his suggestions should be at least as useful to the librarian in industry as to the public reference librarian, and his paper gives also a hint of the extent to which inquiry is still required before any attempt is made to set up a system of regional reference libraries in Great Britain.

The Earl of Elgin and Kincardine, vice-president of the Scottish Council for Development in Industry, who opened the symposium on library service to industry, was concerned to provide a national background for the discussion, and, like Mr. Wilkie, stressed the dominant part of science in industrial production and expansion and the need for efficient library service to enable the scientific worker—and indeed the administrator—to do the best work of which they are capable. He gave, moreover, just a hint of the contribution which library service can make to the task of adult education and the bearing of this not merely upon industrial productivity but also upon the social satisfactions which, as Dr. Elton Mayo emphasized, go so far to determine productivity. That point was also stressed by Mr. L. R. McColvin in his final reference to the importance of preventing the devaluation of man.

Mr. McColvin was referring to the part which the public library can play in providing the real incentive to use our technical powers to improve productivity by helping to make life interesting; to promote understanding and tolerance, to provide relaxation and enjoyment and disclose opportunities. Whatever the public library system can contribute to the dissemination of technical information or the improvement of industrial efficiency is, and should be, secondary to its function as a means of adult education and the provision of social satisfaction. It would be untoward if its resources and energies were diverted from that primary task, and the papers presented at the Edinburgh Conference give grounds for believing that in any re-examination of the place of the public library in adult education or the direct contribution it can make to the dissemination of technical and scientific information, its social function will be kept firmly in mind, and particularly by the men and women responsible for carrying out that service.

That reassurance is supported by the presence in the Civil Estimates of an entry of £2,000,000 for the acquisition of a site for the National Library. Only £50,000 of this sum is earmarked for 1951–52, and the project is thus a fairly distant scheme, like that for the Science Centre, which is also to accommodate the Patent Office and its Library, extended and modernized to constitute a first-rate central reference library on science and technology. Mr. F. C. Francis, in his paper dealing with the place of the libraries of Government departments, learned societies and research institutes in providing a full library service for industry, indicated that a sub-committee has already completed its report on the scope and plan of the proposed new Central Scientific Reference Library, although the report has not yet been made public. Mr. Francis emphasized, however, that no one library could provide all the service now required, and that the elaboration of scientific library services in Great Britain demands the greatest possible spreading of responsibility. The function of the National Library is to cover the greater part of the field itself and to co-ordinate the activities of the other libraries, seeking to ensure that all fields of information are properly covered.

Beyond the announcement that the proposed Science Centre is to be on a site on the south bank of the Thames, there has been no official pronouncement since Sir Robert Robinson's reference to the scheme in his anniversary address to the Royal Society on November 30, 1950. The site for the National Library has also been chosen, and the Ministry of Works has requested the London County Council to designate for this purpose in its first development plan the area lying opposite the British Museum on the south side of Great Russell Street. It is proposed that eventually the library of the British Museum shall be separated from the museum departments and accommodated in its own building on this site, much as, some seventy years ago, the natural history collections were transferred to South Kensington. Both projects will require many years for completion, and even the detailed planning is scarcely in sight. Nevertheless, Mr. Francis rightly directed the attention of the Library Association to both the short-term and the long-term problems which such projects pose, and to the challenge they offer to constructive thinking as well as to co-operation. That challenge should be taken up by the scientific worker and technologist as well as the librarian, and indeed by all who appreciate the large part which libraries can play in the dissemination and assimilation of our scientific and technical knowledge. As Mr. Francis indicated, prime importance is attached to the whole matter by the Government; but if the opportunities are to be utilized to the full and all obstacles to achievement overcome, the Government will require the sustained support over a period of years of informed opinion in scientific, technical and industrial circles.

RESEARCH ON BRICK-MAKING

NEW RESEARCH LABORATORIES OF THE LONDON BRICK CO., LTD.

OVER a large area of Great Britain the fletton brick has won its place as the cheapest common brick of the building industry, and an annual output of more than 2,000 million is nowadays achieved by the group of brickworks situated on the Oxford clay in the districts lying mainly around Bedford and Peterborough. In any manufacturing industry operating on this scale it is to be expected that there would be many problems calling for research, and a notable advance has recently been made by the largest fletton manufacturer, the London Brick Co., Ltd., which has recently opened new research laboratories at its Stewartby works near Bedford. The building, which was designed by Mr. C. C. Handisyde, provides efficient accommodation for the strong research team that has been built up since the War and, in addition, includes a display hall, library, and directors' conference and dining rooms. It is perhaps significant of the changes which are coming about in even the more traditional of our industries that accommodation for the Company's directors should be provided in close association with the research laboratories.

The laboratories are, naturally, built of brick. They are on an ample site and are designed in three wings on one floor on a flexible plan which will facilitate any future extensions that may be needed. Offices and small laboratories open off central corridors, and the lessons of modern school design have been utilized in that the larger laboratories obtain cross-ventilation and additional lighting over the corridors.

Other interesting features are the use of ceiling heating-panels in the laboratories to avoid the loss of valuable wall and floor space which other forms of heating would have required, and the imaginative use of bright, pleasant colours throughout the building in the decorations. Even the service pipes, which, owing to the nature of the site, could not be accommodated in under-floor ducts, are picked out in various colours in accordance with recommendations issued by the British Standards Institution.

Much of the research work is aimed at improving both the understanding and the operation of the manufacturing processes used in the Company's works, and studies are in hand on the conditioning and grinding of the clay, on the methods of pressing it into green bricks, and on the drying and firing processes involved. It is something of a surprise to find a well-equipped fuel technology laboratory devoted mainly to a study of the fuel content of the natural Oxford clay. Theoretically, the organic content of most of the clay used in the works is sufficient to produce all the heat needed for burning the clay. In fact, on account of the unavoidable inefficiencies of the burning process, some additional fuel has to be provided; but this is only a quarter of that needed for burning most other types of bricks. This is a matter of great economic importance in the fletton industry.

As an essential part of the research on plant and methods, a close statistical watch is kept on the qualities of the bricks emerging from the various works. By this means the effects of changes both in the manufacturing processes and in the nature of the raw clay can be accurately followed. Research of this kind is badly needed in a group of industries which are normally regarded as falling outside the field of chemical engineering, and it may well be that this pioneering work by the London Brick Co. will lead other industries to make similar efforts.

Work of a much more fundamental character is also being done. In association with a detailed geological survey of the Oxford clay deposits, a study has been commenced of the constitution of the clay. Differential thermal analysis is being used for the identification of clay minerals, and provision has been made for the utilization of X-ray techniques at a later stage. These are essentially long-term investigations and represent an imaginative and long-sighted view by the Company of its research activities.

In addition to the work concerned directly with brick manufacture, there is also some research in hand on processes designed to produce a light-weight aggregate for concrete by the bloating of clay, and other clay products of cellular structure. Attention is also given to the utilization of by-products.

Mode of Action of Antibiotics in Stimulating Growth of Chicks

The stimulating effect on chick growth of antibiotics given by mouth has been reported by Stokstad and Jukes[1] and many other workers. Their finding has been confirmed at Reading[2] on several occasions with a variety of diets including practical rations, but not at Greenford, where only practical rations were tested.

The first set of results reported here was obtained independently in the two laboratories. The diet was a practical chick-rearing meal to which procaine penicillin was added to supply 25 mgm. of the antibiotic/kgm. Day-old Rhode Island Red × Light Sussex chicks were used in both laboratories, but were obtained from different sources. Their mean body-weights in grams after three weeks on the diets were:

Laboratory	No. of chicks/group	Without penicillin	With penicillin
Greenford	10 (mixed sexes)	181	183
Reading	20 ♂	143	191

The second experiment was designed to eliminate sources of variation between the two laboratories. One large batch of National Baby Chick Mash was obtained and divided between them. Similarly, equal groups of cockerel chicks (Rhode Island Red × Light Sussex) from the same supplier were distributed to each on the day of hatching, and their housing conditions were made as nearly as possible the same. The chicks were given the experimental diets for three weeks and their mean body-weights in grams at the end of this period were:

Laboratory	No of chicks/group	Without penicillin	With penicillin
Greenford	20 ♂	188	191
Reading	20 ♀	167	192

The reasons for this marked discrepancy between results in the two laboratories is being investigated further; but the findings so far support the suggestion that the growth-stimulating effect of antibiotics results from their suppression of micro-organisms detrimental to the host. It is possible that at Reading, and in other laboratories, where chicks have been kept regularly for a number of years, such organisms may have become established, with a slightly retarded rate of growth as their only manifestation. Chicks are not normally kept in the Greenford laboratories, and it is therefore unlikely that such organisms would be present there. If this explanation proves correct, it could certainly account for some of the dramatic results obtained by many workers with antibiotics in practical poultry management.

Quite possibly, with chicks deprived of the animal protein factor or other vitamins, antibiotics may stimulate growth also by creating in the gut conditions more favourable to the synthesis and uptake of missing factors.

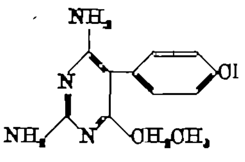
A 2:4-Diamino Pyrimidine in the Treatment of Proguanil-resistant Laboratory Malarial Strains

A series of 2:4-diamino pyrimidines substituted in the 5- and/or 6-position has recently been described[1] as having activity against malaria infections of laboratory animals. In particular, 2:4-diamino-5-*p*-chlorophenyl-6-ethyl pyrimidine (I), termed 50–63 here, showed a high degree of activity.



I

This compound has been tested against strains of malaria parasites showing experimentally induced resistance to proguanil. Its activity against these resistant strains falls little short of that which it exercises against normal strains.

Three resistant strains were used in these experiments. The proguanil-resistant *P. gallinaceum* was obtained from the Liverpool School of Tropical Medicine and is strain 6 as described by Williamson and Lourie[2]. This strain was tested for proguanil-resistance before proceeding further and was found to be at least 55 times more resistant to the action of proguanil than the normal sensitive strain. (Minimum effective dose for proguanil is 0·9 mgm./kgm. for the normal strain and more than 50 mgm./kgm. for the resistant strain, the minimum effective dose being defined as the dose which effected a 50 per cent reduction in parasitæmia compared with untreated controls, this being estimated graphically from dose-response curves.)

Two drug-resistant strains of *P. berghei* were used: the first a strain which had been subjected to sub-curative doses of proguanil, and the second to sub-curative doses of sulphadiazine. The method of inoculation and dosing is similar to that described by Goodwin[3]. After their respective courses of treatment, both strains were tested for proguanil- and sulphadiazine-resistance along with the untreated parent strain.

It had previously been shown[4] that treatment of *P. gallinaceum* infections in chicks by sub-curative doses of sulphadiazine had very quickly induced a high degree of proguanil-resistance in that strain, even before sulphadiazine-resistance became mani-

Table 1. Tests of Resistance of Proguanil- and Sulphadiazine-treated Strains of *P. berghei*

Experiment	Strain	Min. effect. dose proguanil (mgm./kgm.)	Min. effect. dose sulphadiazine (mgm./kgm.)	Degree of resistance*
1†	Parent	5·2	—	3·8
	Proguanil-treated	20	—	
2	Parent	—	0·07	1·1
	Proguanil-treated	—	0·08	
3	Parent	5·8	0·05	1·7 for proguanil, 3·2 for sulphadiazine
	Sulphadiazine-treated	10	0·16	
4	Parent	5·2	0·03	3·8 for proguanil, 4·3 for sulphadiazine
	Sulphadiazine-treated	20	0·13	

* Degree of resistance is expressed as the ratio of the minimum effective dose for resistant strain to that for parent strain.

† Exp. 1: after twelve treated passages. Exp. 2: eight months after exp. 1; strain treated occasionally with maximum tolerated dose of proguanil between experiments. Exp. 3: after seven treated passages. Exp. 4: after nine treated passages.

fest. Table 1, which summarizes these preliminary experiments, shows that the sulphadiazine-treated strain of *P. berghei* has also attained some degree of resistance towards proguanil.

The results in Table 1 also show the proguanil-treated strain to have become resistant to proguanil treatment. The ratio is of necessity small owing to the low activity of proguanil in *P. berghei* infections and its high toxicity to mice. It is also interesting to note that while the sulphadiazine-treated strain had quickly attained resistance to proguanil, the proguanil-treated strain showed no resistance to sulphadiazine. Similar work by Bishop and McConnachie[4] showed that cross-resistance to sulphadiazine by proguanil-resistant *P. gallinaceum* strains is only attained after prolonged treatment with large doses of proguanil.

Using these three resistant strains and the corresponding normally sensitive strains, 50–63 was assayed by methods previously described[1,5] and the minimum effective doses of the compound against each particular strain determined as above (see Table 2).

Table 2. Activity of 50–63 against Proguanil-resistant *P. gallinaceum* and *P. berghei*

Drug	Strain	Min. effect. dose (mgm./kgm.)	Degree of resistance
Proguanil	*P. gallinaceum*—parent	0·9	>55
	P. gallinaceum—proguanil-resistant	>50	
	P. berghei—parent	5	
	P. berghei—proguanil-resistant	>20	>4 for 'proguanil strain' 3·5 for 'sulphadiazine strain'
	P. berghei—sulphadiazine-resistant	17·5	
50–63	*P. gallinaceum*—parent	0·03	2·3
	P. gallinaceum—proguanil-resistant	0·07	
	P. berghei—parent	0·02	
	P. berghei—proguanil-resistant	0·06	3 for 'proguanil strain' 1 for 'sulphadiazine strain'
	P. berghei—sulphadiazine-resistant	0·02	

From Table 2 it appears that cross-resistance does not occur; 50–63 largely retains its high degree of activity against strains which respond little or not at all to maximum tolerated doses of proguanil. Further experiments show that *P. gallinaceum* does not readily become resistant to 50–63 after treatment with subcurative doses of that compound, in direct contrast to the ease with which proguanil-resistance is produced[6,7]. In the present series, an offshoot of the *P. gallinaceum* strain was treated through fourteen successive passages with a total of 95 doses of 50–63 at a dose of 0·04 mgm./kgm., approximately the minimum effective dose. At the end of this course of treatment, the minimum effective dose of 50–63 was determined for both the parent and treated strains (see Table 3).

Table 3. Test of Resistance of Parent and 50–63-treated Strains of *P. gallinaceum* to 50–63

Strain	Min. effect. dose of 50–63 (mgm./kgm.)	Degree of resistance
Parent	0·02	2·5
50–63-treated	0·05	

These results indicate the treated strain to be two and a half times more resistant to treatment with 50–63 than the normal strain. Knoppers has shown[8] that treatment of *P. gallinaceum* infections with quinine results after twenty-six weeks in the development of two-fold resistance; further treatment did not result in increased resistance. 50–63 may behave similarly and produce a low degree of resistance not easily increased by further treatment.

A more detailed and extended account of these observations will be published elsewhere.

Formation of Extra-cellular Nitrogen Compounds by Fungi

In the course of work in this Laboratory on the nitrogen metabolism of mould fungi, it has frequently been observed that much less than the total amount of nitrogen supplied initially in the medium in the form of nitrate or ammonium salt is recovered in the fungus mycelium, although a high level of readily assimilated carbohydrate is present in the culture medium. Similar results have been obtained by other workers[1]; but it is not clear whether they are to be explained by incomplete assimilation of the nitrogen source or by the formation by the fungus of complex nitrogen compounds which either remain in, or are excreted into, the medium. A quantitative study of the uptake of inorganic nitrogen by fungi was therefore undertaken, using in the first place a strain of *Scopulariopsis brevicaulis*.

The fungus was grown in still culture in small conical flasks on a liquid synthetic medium containing 5 per cent glucose (AR), mineral salts, trace elements, and inorganic nitrogen as either potassium nitrate or ammonium sulphate. The ammonia medium also contained 1 per cent sodium succinate, the addition of which has been found necessary to ensure good growth on ammonium sulphate with this particular strain. The nitrogen source was sterilized separately from the other components of the culture medium. Each flask received exactly the same quantity of nitrogen initially. The disappearance of nitrate and ammonia from the medium was followed at intervals during growth of the fungus. Ammonia was determined by titration after distillation in Conway micro-diffusion units. Nitrate was determined as ammonia after reduction by Devarda's alloy. Simultaneous determinations of the total nitrogen in the medium were made by micro-Kjeldahl (nitrate, if present, being previously reduced with iron).

Differences were found between the total nitrogen and the inorganic nitrogen (nitrate or ammonia) in the medium which indicate the formation of extracellular 'organic nitrogen' during the growth of the fungus, as the accompanying figures show.

Nitrogen source	Amount of nitrogen per flask initially (mgm.)	'Organic-nitrogen' formed per flask (mgm.)											
		Days											
		0	3	4	5	6	7	10	12	15	16	17	23
NH_4	6·1	–	0·3				1·2	1·3	1·2	1·4			1·5
NH_4	6·8	–	0·3	0·7	0·9	1·4	1·6	1·4				1·6	
NO_3	6·6	–				0·7	0·9	1·2			1·4		

The nitrate and ammonia had completely disappeared from the medium by the sixth or seventh day, and it is thus evident that most of the formation of 'organic nitrogen' accompanies the active assimilation of inorganic nitrogen by the young growing mycelium. Thereafter the 'organic nitrogen' remains rather steady, possibly showing a slight tendency to increase. Other experiments have shown that the formation of extra-cellular 'organic nitrogen' takes place over the normal *p*H range at which growth occurs, and also with differing carbon/nitrogen ratios of the starting medium. It also takes place in shake culture, showing that it is not associated only with the special conditions of still culture.

At least 90 per cent of the 'organic nitrogen' is dialysable and therefore does not consist of extracellular enzymes. It gives strong reactions for α-amino-nitrogen when tested with ninhydrin after removal of any free ammonia. Paper chromatography indicates at least two ninhydrin-reacting substances in culture filtrates of the ammonia medium. One of these substances, but not the other, is also present in filtrates of the nitrate medium. These substances have not yet been identified, nor is it known what proportion of the 'organic nitrogen' is amino-nitrogen.

The formation of extra-cellular nitrogen compounds during the assimilation of ammonia or nitrate in the first stages of growth has been shown quantitatively and qualitatively (appearance of ninhydrin-reacting compounds) for a number of other fungi, including strains of *Penicillium griseofulvum*, *P. chrysogenum*, *Aspergillus niger*, *Trichoderma viride* and *Syncephalastrum racemosum*. The phenomenon thus appears to be of general occurrence, as is confirmed by a number of incidental references in the literature[1-4].

These observations are of considerable significance for the general problem of nitrogen metabolism in fungi. They show that the assimilation of inorganic nitrogen by these organisms is normally accompanied by the conversion of a surprisingly high proportion of the available nitrogen (10–20 per cent) into compounds which are not accumulated in the mycelium. The relation of these compounds to the process of assimilation, and whether they are to be regarded as excretion products, or as playing a more essential part, are questions which can only be discussed in the light of fuller knowledge. Further experiments on this problem are in progress and will be reported in detail elsewhere.

Photo-Inactivation of the Plant Hormone Indoleacetic Acid by Fluorescent Substances

The fact that riboflavin and eosin, which are known to determine the photo-inactivation of indoleacetic acid[1,2], are both fluorescent, led us to investigate whether other fluorescent substances would also be effective in sensitizing such a reaction. Quinine sulphate, æsculin and 2,3,5-triphenyl tetrazolium chloride were tested. It was found by both chemical and biological experiments that these compounds were all active. These substances are colourless, but fluoresce with a visible colour, absorbing light in the ultra-violet region. They are not related chemically, fluorescence being apparently the only property common to them. The present experiments do not necessarily show that there is a direct cause-and-effect relationship between fluorescence and the capacity of inducing the photo-inactivation of indoleacetic acid.

Since many fluorescent substances are of natural occurrence in plants, it seems possible that they play a physiological part in plant growth reactions brought about by light. It also seems that this inactivation of auxin would explain the experimental results of many authors[1] who have treated plants with fluorescent substances.

As to the mechanism of the *in vitro* destruction of indoleacetic acid, it seems that there is always oxidation of this compound, which gives off hydrogen to an acceptor. This can be easily demonstrated by adding a few drops of methylene blue to the reaction-mixture (indoleacetic acid–fluorescent compound). The blue colour disappears within a few minutes of exposure to sunlight. In some instances (sensitization by riboflavin) atmospheric oxygen is required[3]. In other cases (for example, with quinine sulphate), oxygen decreases the reaction-rate. The reason for this is not yet understood.

In the case of catalysis by quinine sulphate, the reaction mixture becomes turbid upon exposure to light, by formation of a compound with lower solubility in water; this compound is ether-soluble. After evaporating off the ether, there remains a pink-brown residue with a strong smell of fæces.

It is possible that one step of the transformations brought about by light is the formation of skatole, by side-chain degradation of the indoleacetic acid molecule.

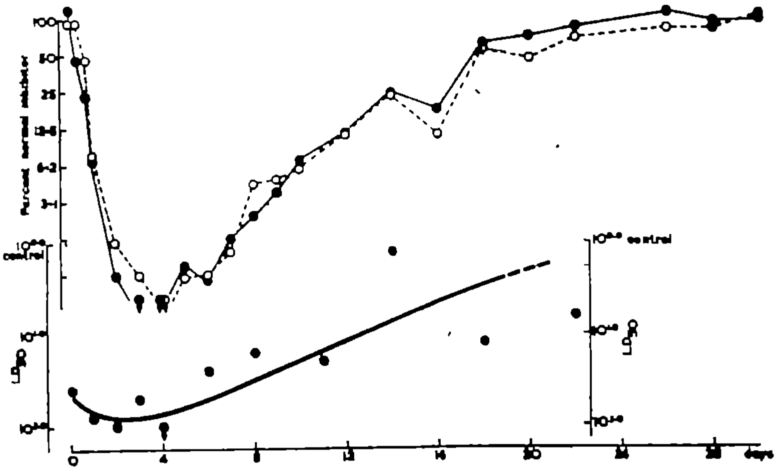
Protection by Receptor-destroying Enzyme against Infection with a Neurotropic Variant of Influenza Virus

In 1948, Stone reported that infection by influenza viruses of embryonated hens' eggs after allantoic inoculation[1], and of mouse lungs after intranasal instillation[2], could be prevented by pretreatment of the exposed cells with the receptor-destroying enzyme of *Vibrio choleræ*[3]. It seems worth adding to these observations the finding that death of mice from infection by a neurotropic variant of influenza virus, neuro-*WS*[4], can be similarly prevented by pretreatment of the mice with an intracerebral injection of receptor-destroying enzyme, and that the return of susceptibility to infection, following a single inoculation of receptor-destroying enzyme, runs roughly parallel to the return of inhibitory activity of the brain[5] to influenza virus hæmagglutination.



Upper graph. Destruction of *HA*-inhibitor in the right (continuous line) and left (dotted line) cerebral hemispheres, following inoculation of receptor-destroying enzyme into the right hemisphere. *Lower graph.* The number of control-mouse *LD*50 required to kill 50 per cent of the mice, when challenged with neuro-*WS* at various times after receiving receptor-destroying enzyme

Groups of 4–5 weeks old mice were inoculated in the right cerebral hemisphere with 12,000 units[6] of purified[7] receptor-destroying enzyme in 0·03 ml., two hours to twenty-two days before being challenged by intracerebral inoculation of neuro-*WS* into the right hemisphere. The times of receptor-destroying enzyme inoculations were so arranged that challenge occurred on the same day for all groups and could, therefore, consist of titrating a single neuro-*WS* allantoic fluid in each group of mice (four mice being used per 0·5 $\log_{10}$ dilution). The mice were observed for twelve days after challenge, at the end of which time all surviving mice appeared perfectly healthy. Protection was estimated by the degree of reduction in the titre[8] (*LD*50) of the neuro-*WS* from the level found in a comparable group of mice which had received no pre-treatment. Afterwards, it was shown that receptor-destroying enzyme which had previously been inactivated by heating at 70° C. for one hour had no protective action.

The above experiment was done in conjunction with a study of the destruction *in vivo*, by a similar dose of receptor-destroying enzyme, of brain inhibitor to heated Lee[9] hæmagglutinin. Hæmagglutinin-inhibitor was measured in saline suspensions of each cerebral hemisphere of four mice, at various intervals after inoculation with receptor-destroying enzyme, and the geometric mean of the titres for each side was compared with the geometric mean titre of thirty-two normal hemispheres. So that dissemination of the receptor-destroying enzyme throughout the brain should not be aided by the process of preparing the brain suspensions, all brains were heated at 62° C. for one hour before they were ground up and suspended in saline. Suitable control experiments had shown that this procedure resulted in adequate inactivation of receptor-destroying enzyme. It follows that the observed degree of inhibitor destruction (more than 99·6 per cent) must represent the proportion of brain inhibitor which is accessible to receptor-destroying enzyme inoculated intracerebrally.

The accompanying figure shows that approximately a hundred control-mouse *LD*50 were required to kill 50 per cent of the mice which had received receptor-destroying enzyme less than four days before challenge, and that susceptibility gradually returned after four days. The figure also shows that the same amount of receptor-destroying enzyme produced marked destruction of hæmagglutinin-inhibitor in both hemispheres; this destruction was greatest on the fourth day and was followed by a very gradual regeneration of inhibitor running roughly parallel to the return of susceptibility to infection.

Inhibitory Action of Artificial Light on the Sexual Season of the Ewe

Recent studies on photoperiodicity have been undertaken in an attempt to hasten the onset of the sexual season of sheep[1-4], to extend the lactation period in goats, to accelerate the onset of oestrus in thoroughbred mares and to advance or prolong the egg-production season in pheasants[5]. Attempts to inhibit the sexual season are of considerable importance in solving certain problems of refractoriness of the gonads in the physiology of reproduction. Yeates[3] has shown that the cessation of the sexual season of Suffolk sheep occurs after 14–16 weeks exposure to an increasing plane of artificial light.

Two series of experiments were carried out to inhibit the sexual season of the ewe by artificial light. During the hours of daylight, artificial light was not used; control animals were available and ochred vasectomized rams were used for detecting oestrus. The term 'latency of cessation' denotes the period elapsing from the start of light treatment to the date of the last oestrus exhibited.

(*A*) Grade Suffolk ewes were exposed to light continuously from November 1, 1950. They were previously running on pasture under natural conditions of daylight until their sexual season had reached its height (per cent oestrus = 100). The experimental ewes were experiencing oestrus regularly but came off season some eight weeks earlier than the control. The date of cessation in the experimental group ranged from January 4 to February 1, with a mean of January 21 (21 ± 1·7), while in the control group the end of season ranged from February 7 to April 20, with a mean of March 17 (76 ± 5·7). The latency of cessation in the experimental group was twelve weeks, and the control ewes came off season when the natural daylight length was twelve hours. The length of cycle (17·4 days), duration of oestrus (36 hr.) and the frequency of silent heat (5 per cent silent heats expressed as a percentage of the total number of heats theoretically possible) were not significantly different in experimental and control groups.

(*B*) Œstrous ewes of six pure breeds (Blackface Mountain, Border Leicester, Dorset Horn, Romney Marsh, Suffolk and Welsh Mountain) and of one first cross (W.M. × D.H.) were exposed to a constant daily ration of 16 hr. light : 8 hr. darkness (long days) starting on September 4. They were previously subjected to a constant daily ration of 8 hr. light : 16 hr. darkness (short days) for some twenty weeks. The latency of cessation ranged from 6 to 24 weeks, according to the breed. The Dorset Horn and its cross showed the longest latency of cessation, whereas the mountain breeds (Blackface Mountain, Border Leicester and Welsh Mountain) had the shortest, and in Suffolks it was nine weeks. The date of cessation of the sexual season was on an average fifteen weeks earlier than the control.

It is concluded that the previous light treatment may control the maintenance and the cessation of the sexual season; and that either the presence of darkness as such or the contrast stimuli of the change from light to darkness is essential for the continuation of the sexual season of the ewe. The latency of cessation is also controlled by other factors besides light. Breeds of sheep which originated near the tropics have a shorter time-lag reaction to light than those breeds which originated nearer the poles. It seems that younger animals are more readily influenced by artificial light than adults. Individual differences are also shown in the response to light. The time of the year at which the light treatment starts determines the latency of response. The previous light environment is an important factor due to the residual effect of light. Both the ratio and rhythm of light control the speed of the response.

The mechanism of the light-stimulating action on the gonads is believed to be via the hypophysial-portal system[6], while the mechanism of the light-inhibitory action has not yet been elucidated.

This work was carried out in the Animal Research Station, Cambridge, during study leave granted from Fouad I University, Egypt. Detailed results of experiment (*B*) will appear elsewhere. Thanks are due to Dr. John Hammond for providing facilities and for his continuous encouragement.

Control of Cauliflower Mosaic Virus

Caldwell and Prentice[1] emphasized in 1942 the value of seed-bed isolation in the control of cauliflower mosaic virus, which in Devon has seriously reduced yields of broccoli. Experimental work at this College has shown that infection in the seed-bed can still be the main cause of reduced yield, even when conditions favour extensive spread of virus in the field after planting.

Three varieties of broccoli, Extra Early, *A*6 and *B*1, were grown in two seed-beds, one adjacent to an infected seed broccoli crop and one half a mile from any *Brassica* crop. The seedlings were planted out in replicated plots. Although practically all the plants in the experiment developed virus symptoms before they were cut, an analysis of the results shows that plants from the isolated seed-bed gave both heavier yields and higher percentages of marketable heads. As no difference in varietal susceptibility was observed, the three varieties are treated together in the following table.

Comparison of Yields from the Two Seed-beds

Seed-bed	Per cent of curds of diameter more than 2 in. across	Av. total yield per plot (lb.)
Isolated by ½ mile	81	49·5 (s.e. ± 4·7)
Not isolated	44	36 (s.e. ± 2·12)

Fortnightly recordings of the plots showed that there was considerable variation in the expression of symptoms. Plants infected in the seed-bed developed vein-clearing followed by vein-banding symptoms[2], and secondary infections of a similar type were observed in the autumn. From December onwards, increasing numbers of plants showed an additional symptom, consisting of a diffuse mottling of small pale-green circular spots or rings standing out in contrast to the dark leaf background, that developed rapidly in young leaves which had previously shown no symptoms. These spots are suggestive of those caused by cabbage ring spot virus on cauliflowers as described by K. M. Smith[3]; but cross-inoculations on to *Nicotiana* sp. have so far been negative, and no leaves have been observed in which the spots have later become necrotic. The mottling is therefore considered to be a further expression of cauliflower mosaic virus.

An experiment using a systemic insecticide, *bis*-(*bis*-dimethylamino-phosphonous) anhydride, to control the aphid vector *Brevicoryne brassicae* alighting on seedlings from infected plants, showed that while this insecticide sprayed on to plants at a concentration of 0·3 per cent v/v gave an excellent control of the aphids, virus transmission was not inhibited. The experiment was carried out under optimum conditions for virus transmission.

Further work is now in progress.

Relationship of Aphid Density to Altitude

THE dispersal of small insects to high altitudes by convection and turbulence is known to produce an insect-density gradient in which density decreases with height[1,2]. The distribution has never been expressed mathematically; and since the insect population of the air varies considerably from hour to hour, and most of the observations at the different heights were made at different times, mathematical analysis would have yielded little of value.

This handicap has been overcome in recent work, and the mean aerial density of aphids has been measured simultaneously at different heights using traps attached to a barrage balloon cable. The observations were made at Cardington, Beds, in co-operation with the Research and Development Establishment, Ministry of Supply.

Between May 27 and October 8, 1948, trapping with tow-nets was done simultaneously at 50, 250, 500, 1,000, 1,500 and 2,000 ft. above the ground during 08.30–10.30, 11.30–13.30 and 14.30–16.30 B.S.T. on suitable days. The nets had opening and closing devices, trapping only at the correct altitudes and times. Aphid densities (numbers per 10^6 cu. ft. of air) were estimated from the number of aphids caught and the run of wind through the nets[3]. Wind runs were measured with anemometers at 10, 250 and 2,000 ft., values at the remaining heights being estimated by interpolation[4]. Although tow-nets under-estimate density at wind-speeds below about 7 m.p.h., it is possible to make a correction for calm conditions[3,5], and Table 1 shows arithmetical mean density estimates with and without the correction; the two estimates probably encompass the truth.

Table 1. APHID DENSITY/10^6 CU. FT.

Height (ft.)	Arith. mean Corrected	Arith. mean Uncorrected	Mean log (density + 1) Corrected	Mean log (density + 1) Uncorrected	No. 2-hr. runs	Mean wind-speed (m.p.h.)
50	1,584·0	161·9	2·02	1·78	49	7·2
250	851·9	99·7	1·92	1·64	49	7·5
500	67·7	26·0	1·40	1·29	49	8·8
1,000	12·3	9·1	0·87	0·84	47	11·1
1,500	8·7	6·5	0·77	0·75	46	12·9
2,000	4·9	4·6	0·56	0·57	48	14·4

The distribution at any time is determined by the net effect of upward transport by turbulence and downward transport by gravity and biological impulse. It is not helpful to ascribe to an aphid a terminal velocity of fall as it is not an inert particle; but it is possible to obtain an estimate of the rate at which it tends to return to earth—the 'mean clearance-rate'—from a simple extrapolation of turbulence theory known to hold near the ground.

If χ is the density at height z, and ω is the 'mean clearance-rate', then for a quasi-stationary state the balance equation is:

$$\omega\chi = -K\partial\chi/\partial z,$$

where K is the turbulent transport coefficient. Rossby and Montgomery make $K = k_0 u_* z$ (see, for example, ref. 6, p. 247), where k_0 is von Kármán's constant (0·4) and u_* is the shearing velocity near the ground $(\tau_0/\rho)^{1/2}$). Then for any two heights z_1 and z_2,

$$\chi_1/\chi_2 = (z_1/z_2)^{-\omega/k_0 u_*};$$

hence a graph of log χ against log z should yield a straight line of slope $-\omega/k_0 u_*$. Fig. 1 shows the graphs for mean logarithmic density with corrected and uncorrected data, and the lines drawn are good fits down to 250 ft. Departures from the straight lines at lower heights could arise from: (i) sampling errors at the lower wind-speeds near the ground; (ii) an additional re-distribution factor representing the flight behaviour of living insects moving between air and terrestrial habitats; (iii) the source of supply being local and irregular, whereas the higher aphids will have come from larger and more remote areas—possibly biologically different—farther upwind; (iv) the velocity profile departing markedly from its theoretical shape.

From the straight lines, the values of $-\omega/k_0 u_*$ are $-1·2$ (uncorrected) and $-1·5$ (corrected): the order of magnitude of u_* is known to be 15 cm./sec. at the measured mean wind-speed[7]; hence the 'mean clearance-rate' is equivalent to approximately 7 cm./sec. (uncorrected) or 9 cm./sec. (corrected). Both values are much lower than such crude estimates of terminal velocity of aphids as exist; for example, Wellington's curves[8].

During the normal evening decay of flight activity, aphids which are brought near to earth will alight; and if the estimated 'mean clearance-rate' is a measure of the speed of return in the much calmer evening conditions, then the aphids in the lowest 2,000 ft. of the atmosphere should have returned to very low altitudes or to the ground, on the average, in about two hours. This estimated rate of clearance fits in well with observation[9].

For single days and single samplings there are frequent wide variations from the mean distributions represented in Fig. 1.

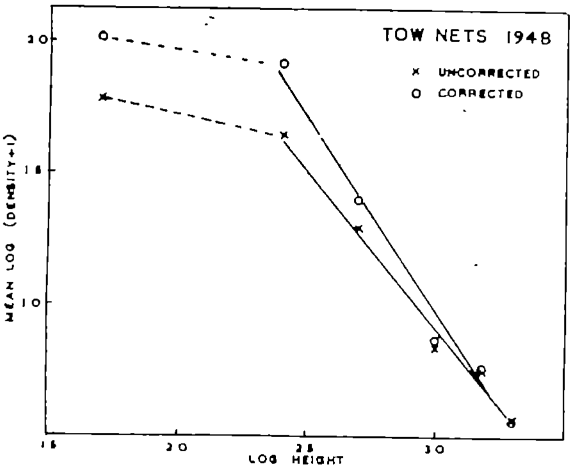

Fig. 1

In 1950 the work was repeated with suction traps, which are considered to be more reliable than tow-nets[3,5]; they were operated at 10, 150, 500 and 1,000 ft. The numbers of aphids caught per hour with each trap may be taken as the density for 132,000 cu. ft., since that volume of air is sampled by a trap in one hour irrespective of wind-speed. The results are scanty, for there were few aphids in 1950; but there are 65 separate hourly occasions between July 13 and 31 which can be used (Table 2). The average wind-speed was about the same as in 1949.

Table 2

Height (ft.)	For 65 hours Total No.	Mean log (No. + 1)	For 7 hours Total No.	Mean log (No.)
10	574	0·78	124	1 25
150	164	0 44	25	0 65
500	26	0·11	11	0 37
1,000	10	0 04	6	0·33

When mean log (catch + 1) is plotted against log (height) the points lie on a straight line between 10 and 1,000 ft., the slope being −0·4 (Fig. 2, lower curve); but there were too many occasions of zero catch at 1,000 ft. for the corresponding point on the graph to have any significance. There were, however, seven hours during which aphids were caught at all heights, and for these no adjustment was made before taking logarithms. The upper curve of Fig. 2 is for these results and has a slope of −0·5, from which the 'mean clearance-rate' is 3 cm./sec.

This changed estimate in clearance-rate may be the result of the change in trapping technique or of different degrees of validity of the simple assumption made in the analysis. As the work with suction traps is being extended, detailed examination of the meteorological factors will be postponed until more results are available.

Chromosome Number and Chromosome Morphology in *Helicophyllum crassipes*

Helicophyllum crassipes (Araceæ)[1] grows as a weed in the coastal belt of Egypt, in localities where the soil is light calcareous sand and where the percentage of salt is low. It is a corm-geophyte which sprouts late in October and flowers during January and February; flowering sometimes extends through March and April. The plant seems to possess a high capacity for seed production.

Chromosome counts and study of chromosome morphology were made in squashes of root-tips and anthers. Feulgen and acetic-orcein methods were used. For pollen grain mitosis Allen–Bouin as fixative and crystal-violet-iodine were used. Pretreatment with 8-oxyquinoline[2] (0·002 mol. per litre for 4 hr.) was also used in root-tip preparations. Material was collected from plants growing naturally.

More than two hundred metaphase plates (polar view) showing clearly the number of chromosomes and their morphology were counted and studied. The accompanying drawings were made from specimens subjected to 8-oxyquinoline pretreatment, which shows the constrictions clearly. This effect is due to the shortening of the arms of the chromosomes and resulting elongation of the constrictions.

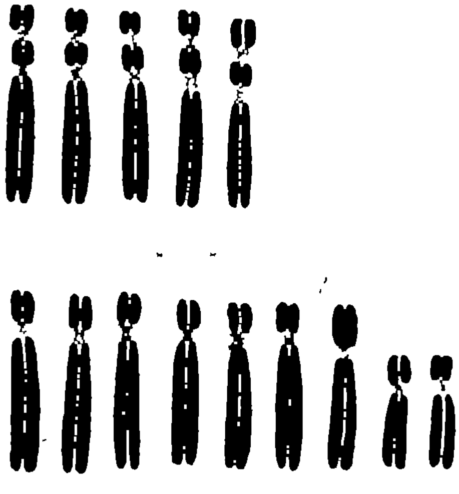

Fig. 1. Diagrammatic drawing of the chromosomes of *Helicophyllum crassipes* showing their comparative length and their constrictions

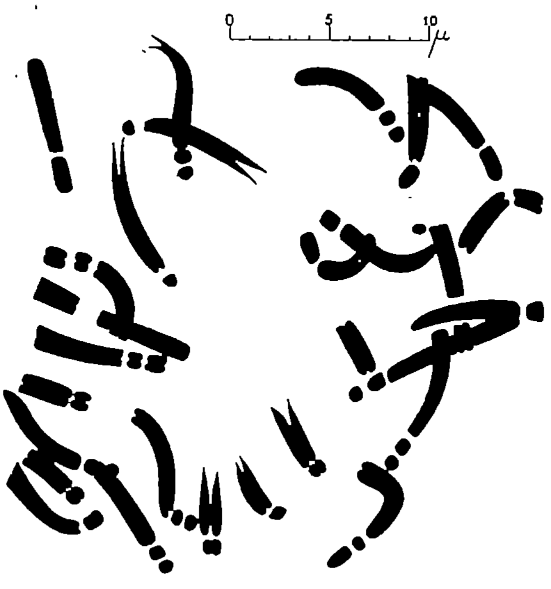

Fig. 2 Camera lucida drawing of a metaphase plate, polar view, using Leitz apochromatic objective, 90 ×, and compensating eyepiece 30 × (original magnification, 7,600 × ; reproduction, 2,500 ×)

In root-tips the diploid number was found to be 28. In every case it was possible to find a homologue for every chromosome, giving a definite count of 14 pairs.

The chromosomes were classified according to their morphology as: (1) chromosomes with two constrictions (primary and secondary); (2) chromosomes with a primary constriction only.

The primary constriction was invariably submedian in chromosomes with secondary constrictions, whereas in chromosomes with one constriction only it was subtelomeric. No chromosomes with strictly median or strictly telomeric primary constriction were noticed.

The chromosomes were also classified according to their length into long and short ones. Those with two constrictions were almost all long, except one pair which was slightly shorter than the rest. Those with a primary constriction only were also of the long type, except two pairs which were distinctly shorter (Figs. 1 and 2). The number of chromosomes with two constrictions is five; with one constriction only, nine.

In some nuclei a small, almost spherical chromatin body (staining like the chromosomes) was noticed. No explanation can yet be given as to the origin and occurrence of this body.

Polyploid nuclei with chromosome number higher than $2n$ were occasionally noticed; in a few cases the number was found to be 56, that is, tetraploid.

In pollen grains, mitosis takes place early when the grains are still young and before the thickening of the exine. Chromosome counts were 14. The chromosomes were found to agree in morphology with those of diploid cells in root-tips.

Nitrogen Nutrition of Clover

VIRTANEN and collaborators[1,2] and Ghosh and Burris[3] have shown under aseptic conditions that red clover is able to make good growth when supplied with combined nitrogen in certain organic forms (for example, several amino-acids). Virtanen and von Hausen[1] reported, however, that white clover grew poorly on organic nitrogen. The finding that these closely related plants differed radically in their nitrogen requirements is of theoretical and practical interest, and has been further investigated by us.

Non-nodulated plants of red and of white clover (*Trifolium pratense* L. and *T. repens* L., respectively) were grown from seed entirely enclosed in test-tubes (8 in. × 1½ in. in size) plugged with cotton wool and containing an agar rooting-medium made up to the nitrogen-free formula of Chen and Thornton[4]. To this basal medium various forms of nitrogen were added in amounts representing 170 mgm. of nitrogen per litre of medium, the pH being adjusted to 6·5. All precautions were taken to secure asepticity in the cultures, the degree of achievement of this being judged chiefly by visual inspection of the agar medium during the course of the experiments. Very few cultures had to be discarded because of contamination.

Form of nitrogen supplied	Red clover		White clover	
	Increment in dry wt.*	Increment in nitrogen content*	Increment in dry wt.*	Increment in nitrogen content*
Ammon. nitrate	64	3·9	79	4·4
Ammon. sulphate	66	3·0	78	3·9
Potas. nitrate	64	3·2	53	2·9
l-Asparagine	78	4·5	90	4·6
l-Aspartic acid	27	1·9	90	3·3

* Mean increases (in mgm. per tube) over the corresponding values for control tubes (no combined nitrogen added) which were as follows (again as mgm. per tube): dry weight 61 (red), 35 (white), nitrogen content 1·0 (red), 0·6 (white). Each tube-culture contained 4–7 plants of red or 6–9 plants of white clover, with 8 tubes for each treatment, and 6·3 mgm. combined nitrogen was originally added to the agar medium of each tube.

After ten weeks growth under summer conditions, the dry weight (by heating at 95° C.) and total nitrogen were found for the plants from each tube. The results of the main experiment are presented in the accompanying table. Statistical analysis confirms that in both clovers the dry weight of plants receiving asparagine was significantly higher (at $P = 0.05$) than that attained with inorganic nitrogen, while in white clover the same applies to aspartic acid. Similar analysis of the results for nitrogen content shows that asparagine was absorbed as readily as (in white clover) or more readily than (in red clover) the most freely absorbed form of inorganic nitrogen, namely, ammonium nitrate.

These results fail to confirm that white clover is inferior to red in its ability to utilize organic nitrogen, and, in fact, tend in the opposite direction. The reasons for this and other divergences from the findings of Virtanen and von Hausen[1] are not immediately obvious, and may not be revealed until fuller study of the conditions affecting uptake of organic nitrogen by plants has been made. Meanwhile, it appears doubtful whether there is any major difference in the nitrogen requirements of the two clovers.

This question is relevant to studies such as those of Bond and McGonagle[5], where non-nodulated plants of different species of clover were grown as standards against which the effectiveness of different strains of the nodule organism in fixation of atmospheric nitrogen was assessed. In future work of that type it is probable that an organic compound such as asparagine could with advantage be provided as the source of nitrogen for the standard plants.

The above experimental work was carried out while one of us (J. T. V.) was holding a British Council scholarship.

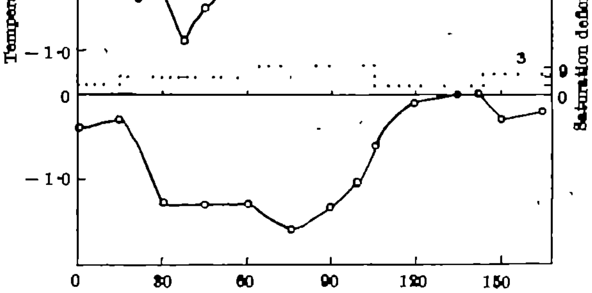
Body-Temperature of Small Insect Larvæ

Laboratory experiments carried out in the autumn of 1950 appear to support remarks made by Dr. D. A. Parry[1], to the effect that on general grounds he considers that various physical factors play a greater part than biological ones in determining the body-temperatures of small poikilothermal animals.

Using apparatus in which air temperature and rate of flow could be held constant, the variation of the air saturation deficiency (in the absence of radiant heat) produced considerable fluctuations in the internal body-temperatures of lepidopterous and hymenopterous larvæ. In the case of smooth-skinned larvæ of *Tenthredopsis litterata* Geoffr. (Hymen. Tenthredinoidea), the divergence of body-temperature with respect to air-temperature at the time of humidity change (graph 1) will be noted to resemble closely the fluctuation in the internal temperature of a piece of clay of similar size and shape when the latter is submitted to comparable environmental changes (graph 2). The divergence is therefore ascribed largely to evaporation and condensation at the outer surface of the larval integument, rather than to a mechanism involving gain or loss of internal fluids. This latter process can scarcely be the means in the case of the clay model; nor is it clear, in the case of the larva, that gain of internal water can occur quickly enough to produce the abrupt rise in temperature. This interpretation is emphasized by a comparison of the curves at such times as the environmental conditions were steady, when the clay is seen to return almost to air-temperature, whereas the larval temperature is depressed slightly below this level, presumably due to the thermal effects resulting from the loss of internal body-fluids not present in the model.



Graph 1. Internal body-temperature variation of *T. litterata* Geoffr. (weight 0·06 gm.)
Graph 2. Internal temperature of a piece of clay
Graph 3. Internal body-temperature of *M. rubi* (weight 2·5 gm.)
Solid curves: internal temperature-difference of larva or clay with respect to an air temperature of 20° C. Dotted lines: saturation deficiency of air in mm. of mercury

Thus while the depression of larval body-temperature below that of the surrounding atmosphere may be at all times in part due to the loss of internal fluids, the major portion of the effect at moments of humidity change is the result of surface phenomena.

Further information with regard to surface evaporation and condensation is provided by an experiment with a 2·5-gm. caterpillar of the fox moth (*Macrothylacia rubi*). The integument of this larva is densely setose and presumably capable of harbouring more moisture than that of a smooth-skinned form. For this reason an extended period of body-temperature depression due to the evaporation of surface moisture might be expected to follow atmospheric humidity change. Reference to graph 3 shows such a state of affairs to exist and a considerable depression to be maintained for some time, after which a slow return to a temperature approaching that of the air might be interpreted as due to the conductive heating effects of the surrounding atmosphere. Had this extended depression been due solely to a loss of internal fluid, which was finally almost completely exhausted, this animal might have been expected to show signs of desiccation; this was not the case. Furthermore, a return to conditions of evaporation, after a period in a moist atmosphere, resulted in a small but steady depression of body-temperature, denoting a continuous loss of fluid, which might be expected if now only internal fluid were being evaporated via some restricted aperture or region. This reinforces the suggestion that the initial extended depression was due mostly to loss of external surface moisture, which was finally almost completely exhausted, so that a short intervening period in a humid atmosphere was insufficient to restore its abundance.

Further details of this work and the methods involved, together with evidence of the importance of considering (*a*) the previous history of insects with regard to surface moisture, and (*b*) the nature and proximity of surfaces on which they may be supported, when making body-temperature observations, will be published elsewhere.

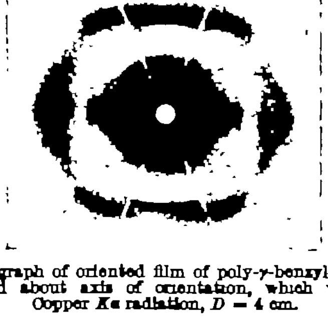
Structure of Synthetic Polypeptides and Proteins

In a recent series of papers, Pauling, Corey and Branson[1] and Pauling and Corey[2-7] have proposed structures for synthetic polypeptides and proteins based on helical configurations of the molecules, and have claimed that these account for the X-ray results of Bamford, Hanby and Happey[8] on the polypeptides, and for the X-ray photographs of a number of proteins. It is the purpose of this communication to indicate that, in fact, the unit cells of Pauling and Corey are unsatisfactory for at least two of the three polypeptides which have been studied in detail, and probably also for α-keratin. Comments on the structures of Pauling and Corey, and these authors' objections to the α_{II}-fold, will be reserved for a later paper from these Laboratories.

The X-ray data on poly-γ-benzyl-L-glutamate are interpreted in terms of a helical structure containing 11 amino-acid residues in three turns and a pseudo-orthorhombic unit cell with $a_0 = 25$ A., $b_0 = 17 \cdot 3$ A. (fibre axis), $c_0 = 14 \cdot 42$ A., and $\beta = 90°$ [2b]. The near meridional reflexions at 5·27 A., which are a striking feature of the diagram[3], are indexed by Pauling and Corey as (131) (230). The inclination of the normal to these planes to the b-axis is 24° 30′, and it may readily be shown that the corresponding reflexions in a fibre diagram should subtend a semi-angle χ at the centre of the diagram of approximately 23°. The observed value of χ from Fig. 3 of the paper by Bamford, Hanby and Happey[3] (upon which the American authors base their unit cell) is about 10°. This diagram was obtained with a film of polymer, the X-ray beam passing through one edge, and it might be considered that the difference between the two χ-values could be explained by double orientation of the molecules. This is not satisfactory, however. In a photograph taken with the beam normal to the film, the 5·27-A. reflexions are not resolved and appear as a polar arc. The equatorial reflexions in this photograph are also drawn out into arcs, showing that although the molecules lie mainly in the plane of the film, their orientation about the direction of stretching is not particularly high. Even so, the polar arc subtends a semi-angle of only 18°. A similar result is obtained from an X-ray photograph of the same film rotated about the direction of stretching (see photograph). Here again the polar reflexions are not resolved, and the polar arc is too short to permit a value of χ as great as 23°. The radial lines on the photograph correspond to $\chi = 23°$ and are obviously outside the main polar reflexion. (For purposes of comparison, the centres of the reflexions on the first hyperbola of the X-ray diagram of poly-γ-methyl-L-glutamate given in Fig. 1 of ref. 3 subtend an angle of 26° 50′. A comparison will show the very considerable difference between these reflexions and the polar reflexion of the accompanying photograph.) A comparison of the dispersions of the strong equatorial reflexions and the polar arc at 5·27 A. shows that the normal to the planes giving rise to the latter are inclined at about 10° to the fibre axis. Similarly, it may be shown that the other three reflexions on the hyperbola (4·48 A., 4·05 A. and 3·60 A.) are too near the meridian to correspond to Pauling and Corey's unit cell, although the diffuse nature of the reflexions makes this point more difficult to demonstrate.



X-ray photograph of oriented film of poly-γ-benzyl-L-glutamate. Film rotated about axis of orientation, which was vertical. Copper $K\alpha$ radiation, $D = 4$ cm.

The same results can, of course, be obtained from reciprocal lattice considerations.

For these reasons we believe that the repeat (or submultiple) along the fibre axis is smaller than that used by Pauling and Corey (5·76 A., that is, $b_0/3$), and is close to 5·45 A., as suggested by Bamford, Hanby and Happey[3]. We conclude that the particular helical structure and unit cell proposed are not consistent with the X-ray data.

The same conclusion applies in the case of the 1 : 1 copolymer of DL-β-phenylalanine and DL-leucine. It has been shown[4] that in the X-ray diagram of highly oriented fibres of this copolymer, the 5·35-A. reflexion is resolved into two near meridional spots, with $\chi = 11°$ 4′. This again is significantly smaller than the value (23°) calculated from Pauling and Corey's fibre repeat of 5·75 A., indicating that the latter is too large. The correct value calculated from $\chi = 11°$ 4′ is 5·51 A.

Thus, the three synthetic polypeptides γ-methyl- and γ-benzyl-L-glutamates, and the copolymer of DL-β-phenylalanine and DL-leucine, have fibre repeats (or submultiples) close to 5·45 A., in excellent agreement with the α_{II}-structure.

We feel that the structure proposed for α-keratin[2e], based on a helix with 3·7 residues per turn, and a fibre repeat of 5·65 A. can be criticized on similar grounds. The corresponding value of χ for the 5·15-A. reflexion is 24° 30′; the total length of the polar arc in porcupine quill corresponds only to $\chi = 15°$.

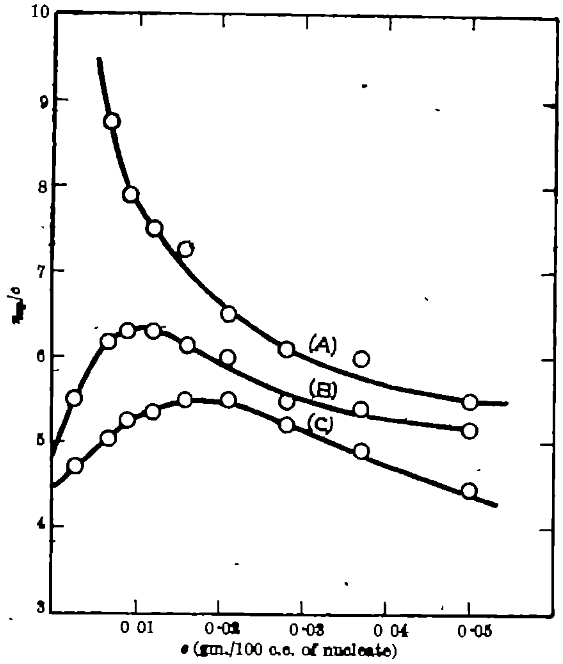
Viscosity of Sodium Thymonucleate

THE viscosity of sodium thymonucleate solutions shows some peculiar characteristics. There is considerable reduction in viscosity of a dilute solution of sodium thymonucleate in presence of neutral salts and alkali. Greenstein and Jenrette[1], as also Tennent and Vilbrandt[2], have postulated the reversible depolymerization of the nucleic acid molecule in presence of neutral salt and alkali. From the measurement of dissymmetry by the light-scattering method, Smith and Sheffer[3] have shown that the nucleic acid molecules coil up in solution in presence of neutral salts. The peculiar viscosity effect may similarly be attributed to coiling and uncoiling of the molecules rather than to reversible depolymerization in presence of salt. Since nucleic acid is a long-chain molecule with the acid groups distributed along the chain, it is to be expected that the sodium salt of the acid will behave as a polyelectrolyte, according to Fuoss's contention[4], in solution, and the peculiar viscosity characteristics may be explained on the assumption of a coiling–uncoiling effect with the extent of dissociation. Viscosity measurements of sodium thymonucleate solution have been under-



taken in this laboratory, and it will be evident from the accompanying graph that the reduced viscosity (η_{sp}/c) increases as the solution is diluted, a result contrary to that for neutral polymers and similar to that of polyelectrolytes.

This phenomenon may be explained as follows. As the solution is diluted, more and more of the sodium salt dissociates and consequently[4] the number of charge-centres on the chain increases. The mutual repulsion of similarly charged centres causes the chain to assume a more and more stretched out configuration with increasing dissociation, that is, with diminishing concentration of thymonucleate, and hence leads to higher reduced viscosity at lower dilution. This hypothesis may be tested by an experiment which it suggests. When a simple one-one electrolyte, sodium chloride, is added to a solution of sodium thymonucleate, we should expect that by a simple mass action effect, under the influence of Coulomb attraction, some of the sodium ions would be drawn back on the polymer chain, that is, the thymonucleate molecule will be less dissociated. When the concentration of sodium chloride is sufficiently high, almost the whole of the dissolved molecules will be undissociated over a considerable range of concentration and will behave like a neutral polymer. This is why Tennent and Vilbrandt[5] obtained a linear curve for reduced viscosity/concentration for sodium thymonucleate solution in presence of 1 per cent sodium chloride. When, however, the concentration of sodium chloride is much lower, sodium thymonucleate molecules will be completely undissociated and behave like a neutral polymer below a particular concentration of thymonucleate; above this concentration, some of the electrolyte groups will undergo dissociation and behave as polyelectrolytes. The reduced viscosity will, therefore, increase with concentration of thymonucleate. Curves *B* and *C* support this view; in presence of sodium chloride, the curves show a hump, the maximum of which occurs at a concentration of thymonucleate where the concentration of sodium ion from thymonucleate is nearly equivalent to that from added sodium chloride. At $3 \cdot 1 \times 10^{-4}$ gm. equivalent of sodium chloride the maximum is at 0·01 per cent or $2 \cdot 8 \times 10^{-4}$ g equivalent of thymonucleate (curve *B*), while a $5 \cdot 3 \times 10^{-4}$ gm. equivalent of sodium chloride th maximum is at 0·0175 per cent or $4 \cdot 9 \times 10^{-4}$ g equivalent of thymonucleate (curve *C*).

Effect of Shear's Polysaccharide on Plasm Clotting

ONE of the agents most effective in causin regression of tumours is the polysaccharide whic Shear and his associates were able, some years ago to extract from the bacterium *Serratia marcescens*[1] This polysaccharide causes a high percentage o regression in the tumours of mice, but unfortunatel it is rather toxic for human beings. If more wer known as to the exact nature of the polysaccharide it might be possible to find other compounds simila in their action on tumours, but less toxic.

Heilbrunn and Wilson[2] have suggested that th polysaccharide behaves like heparin in preventin the division of cells; they have suggested that th polysaccharide may be a compound related to heparin. In cells generally, the initiation of mitosis i accompanied by a sharp increase in protoplasmi viscosity, the mitotic gelation, which is thought o as a protoplasmic clotting. Heparin prevents thu clotting; so, too, do dilute solutions of the bacteri polysaccharide[3].

Is the bacterial polysaccharide of Shear perhap a heparin or a heparin-like substance? Heilbrun and Wilson[2] have found that it gives a metachromati reaction with toluidine blue; this is a positive tes for heparins. Information as to the effect of th bacterial polysaccharide upon blood clotting wa sought in the following manner. Polysaccharid *P*-25, containing 36 mgm. per c.c. (I am indebted t Dr. M. J. Shear for kindly supplying a sample of th polysaccharide to the laboratory), was diluted wit distilled water. Freshly oxalated human plasma wa employed as the substrate, 1 c.c. of 0·1 *M* sodiu oxalate being added to 9 c.c. of blood. Clotting tim determinations were run at 37° C., in standard tubes upon a total volume of 0·3 c.c. (one-third plasma, one-third polysaccharide in distilled water or distille water control, one-third 0·025 *M* calcium chloride). Time was counted from the addition of the calciu chloride until the tubes could be safely inverted. Results were calculated in terms of the contro (exp./control × 100), and are given in the accompanying table.

EFFECT OF SHEAR'S POLYSACCHARIDE ON PLASMA CLOTTING

Polysaccharide (per cent)	Plasma clotting time (per cent control)
3·6	750
1·8	240
1·44	188
1·08	158
0·72	130
0·36	115

Shear's polysaccharide was shown by this method to inhibit the clotting of recalcified plasma; its effect is therefore heparin-like. Comparison with various commercial heparin preparations showed them to be approximately 138–320 times more effective.

This investigation was aided by a grant from the U.S. Public Health Service, administered by Prof. L. V. Heilbrunn.

Surface Tension of Liquid Metals

Atterton and Hoar's[1] communication recalls two papers recently published on this subject. Schytil[2] has shown that the surface-tension σ is related to the melting point T_m and the atomic volume V by

$$\sigma = K_1 T_m V^{-2/3}, \qquad (1)$$

where K_1 is a constant. The other paper, due to Auerbach[3], contains data to show that, for a considerable number of substances, including metals and even liquid helium,

$$\sigma = K_2 \rho v^{3/2}, \qquad (2)$$

where ρ is the density of, and v the velocity of sound in, the substance, K_2 being another constant. As Schytil points out, expression (1) can be converted to one similar to that due to Wen Po[4]:

$$\sigma = K_3 A \nu_D^2, \qquad (3)$$

where A is the atomic weight, ν_D the Debye frequency, and K_3 another constant.

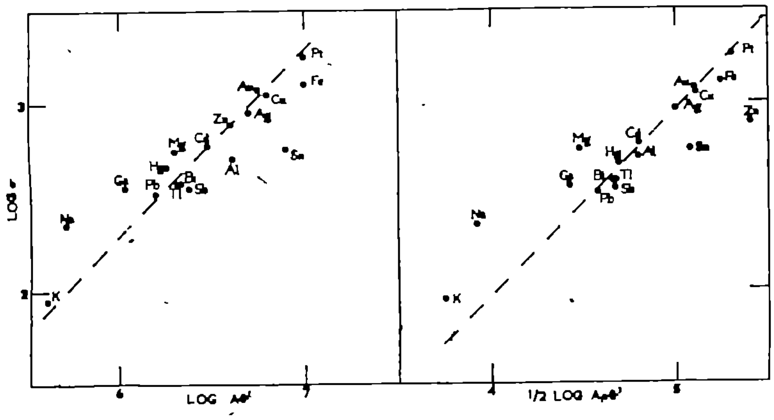
If we postulate (*a*) that the cube of the transverse velocity, c_t, is small as compared with that of the longitudinal velocity, c_l, or (*b*) that in many cases there is a linear relation between the two[5], Debye's expression for the number of oscillators assumes the form:

$$V \nu_D^3 = K_4 v^3, \qquad (4)$$

where V is the atomic volume and K_4 a constant. Combining (4) with (2) and introducing the Debye temperature θ_D instead of the frequency ν_D,

$$\sigma^2 = K_5 A \rho \theta_D^2 = K_5 p, \qquad (5)$$

where K_5 is a constant.



In order to reveal the discrepancies for small values of p, it is better to plot the logarithms of both sides of this equation. The values of ρ are taken from the International Critical Tables; those for θ_D are given by Seitz[6]. The data for σ are obtained from Atterton and Hoar's graph and from the International Critical Tables. They refer to temperatures at or near the melting point. It will be seen that the semi-empirical expression (5) is fairly successful in several instances. If the linearity of the data is compared with that to be expected from equation (3), it will be realized that there is little to choose between the two. The lines have slopes equal to unity: it would seem that slopes somewhat smaller than this would provide a better fit for each set of points. The best-fitting straight lines calculated from the regression coefficients have slopes of 0·861 and 0·856 corresponding to equations (3) and (5) respectively; they are not inconsistent with the theoretical values of unity. The fact that both expressions (3) and (5) are roughly satisfied is probably due to the inaccuracy of the experimental data, and also suggests that the empirical expression (2) is only another form of the one due to Wen Po[4].

In a communication in *Nature* of April 14, Messrs. Atterton and Hoar recorded the conclusion that "surface tension is approximately inversely proportional to atomic volume". May I venture to recall that this is a conclusion which I put forward some thirty-seven years ago, based upon determinations of the surface tensions of some of the commoner metals, which I had made at the Royal Mint, by measuring the depths of depressions in carbon tubes of small bore[1]. By plotting the reciprocals of the surface tensions of these metals against their atomic weights and side by side with their atomic volumes, the resemblance to Lothar Meyer's well-known curve became apparent. The resemblance was even closer when these reciprocals were plotted side by side with atomic volumes raised to the 2/3 power[2]. I felt justified, therefore, in suggesting that the surface tensions of molten metals, like other properties, are periodic functions of their atomic weights and that they vary inversely as some function of their atomic volumes. Now that figures for the surface tensions of more elements are available, it is satisfactory to find that Messrs. Atterton and Hoar have arrived at the same conclusion.

The implication of this relationship with regard to the penetration of liquid metals into compacted sand, to which they refer in the latter part of their communication, has, I think, some analogy to the behaviour of metals on the surfaces of cupels when undergoing cupellation in the process by which gold bullion is assayed. When the surface tension of the metal is lowered by the presence of tellurium, I have shown that the 'cupellation losses', normally allowed for by suitable 'checks', may, in extreme cases, be such that complete absorption of the metal by the cupel may occur[3].

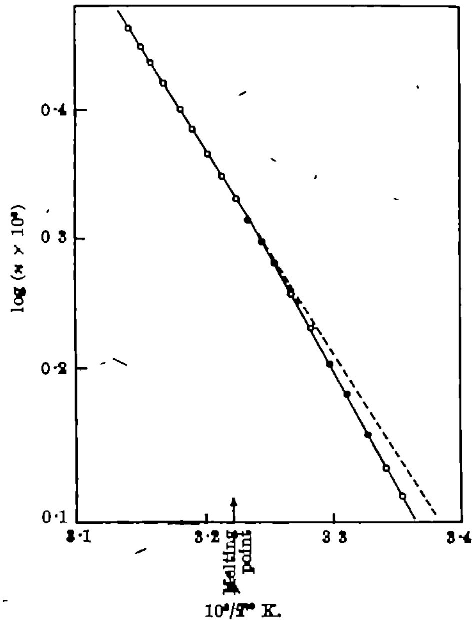
Discontinuities in Supercooled Ionic Melts

During the course of a systematic investigation on the electrochemistry of boron trifluoride co-ordination compounds[1], discontinuities were observed in the temperature variation of viscosity on passing from the normal liquid to the supercooled state. In both temperature regions the viscosity could be expressed by an exponential relation of the form $\eta = \eta_0 \exp(B/RT)$, but the activation energy B was approximately 10 per cent greater for the supercooled state. The temperature coefficient of the specific volume (v) shows no such discontinuity at the melting point, and this fact may be used for emphasizing the discontinuous behaviour of the viscosity by the application of Batchinski's equation[2] $\eta = C/(v-b)$, where C and B are constants. For example, if the fluidity $\varphi = 1/\eta$ is plotted as a function of specific volume for acetoxytrifluoroboric acid, $H[CH_3.CO.OBF_3]$, there is a well-defined discontinuity at a point corresponding to the melting point, 37·5° C. The change in slope is 34 per cent, compared with an increase of 10 per cent for the activation energy B for this compound.

As boron trifluoride complexes are systems for which the activation energies of ionic migration are very similar to those of viscous flow[3,4], it is likely that similar configurational changes occur in the two processes and that ionic mobility at various temperatures will be proportional to the viscosity. It might therefore be expected that the specific conductivity of such liquids would show a corresponding effect at the melting point. This is, in fact, the case as may be seen from the accompanying graph, in which log κ is plotted against $1/T$ for molten acetoxytrifluoroboric acid. The increase in slope at the melting point is 13 per cent. A graph of specific conductivity as a function of specific volume shows the same phenomenon.



Electrical conductivity of molten acetoxytrifluoroboric acid

The ionic compounds formed by boron trifluoride with methyl, ethyl, n-propyl and n-butyl acetates behave in a precisely analogous fashion to the addition compound with acetic acid considered above. The effect, however, is not confined to ionic melts, as Dodd and Hu Pak Mi[5] have shown that plots of log η against $1/T$ for phenyl ether and m-chloronitrobenzene are discontinuous at the melting point. It is consequently of interest to determine whether or not these effects are general in supercooled melts. The data on such systems are rather scattered, but a recalculation of available information shows that the same trend is implicit in the figures of Walden, Ulich and Birr[6] for the viscosity and conductivity of certain molten picrates.

A fuller discussion will be published elsewhere.

Dimensions of the Nitrite Ion

As part of a programme of X-ray investigations of N—O bond-lengths and angles, and in particular for comparison of the bond-lengths in the positive (nitronium)[1] and negative (nitrite) NO_2 ions, the structure of sodium nitrite[2] has been redetermined. Three-dimensional and differential Fourier syntheses (corrected for termination of series errors) give the following dimensions for the nitrite ion :

Bond-length	N—O	1·13(9) A.
Angle	O—N—O	132° 48′

The root mean square error in the bond-length calculated by the method of Cruickshank[3] is ±0·01 A., so that the value of 1·14 A. now found is not significantly different from the value of 1·15 A. for O—N in the nitronium ion in nitrogen pentoxide[4].

Full details of the determination will be published together with those for nitronium perchlorate, which is still under investigation.

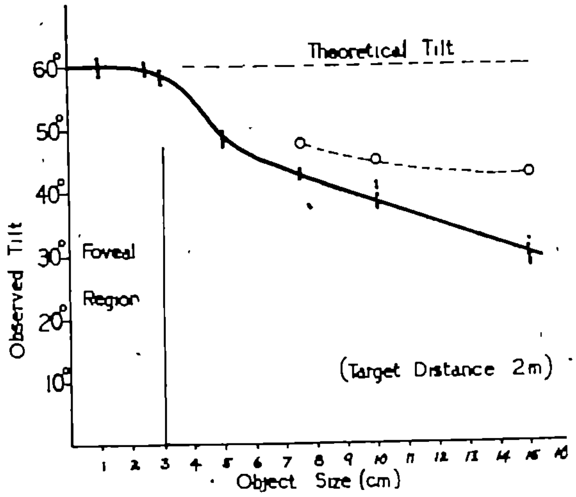
Ocular Scanning and Depth Perception

THE relation between peripheral and foveal vision and the extent to which scanning movements of the eyes are necessary in the perception of three-dimensional space are problems of long standing. Experimental work on stereoscopic vision has been largely concerned with the measurement of stereoscopic acuity, using the three-needle test or one of its modifications, under carefully controlled conditions. Such tests give the minimum resolvable difference in depth which can be perceived by an observer under the given conditions; but they do not explain how the eyes function when they view the normal three-dimensional world. In normal observation of space the point of fixation ranges over a wide field, and the eyes are continuously receiving dissimilar uniocular impressions. It is generally assumed, however, that stereoscopic vision is based upon the stimulation of disparate retinal points, so that consequent on the presentation of unequal uniocular impressions the final perceptual pattern in space is determined by the retinal disparity from purely geometrical considerations. The experiments which are to be described show that this simple geometrical theory does not hold generally, but only if the space object forms an image entirely on the fovea.

A modified form of Wheatstone stereoscope was used to examine and measure the observed stereoscopic effects which resulted from given retinal image disparities. The two unequal uniocular impressions were obtained by using horizontally disposed arrows as targets in the stereoscope. Black arrows on white backgrounds, of equal illumination, were used as targets, the arrows being of equal thickness but of slightly different length. Each arrow was viewed by one eye alone, and the two fused impressions gave a perceptual image directly in front of the observer. This perceptual image was a horizontal arrow tilted out of the subject's frontal plane. The mirrors of the stereoscope were semi-transparent to allow observation of an indicator arrow, mounted on a divided circle, and placed coincident with the perceptual image. By aligning the indicator arrow with the perceptual image, the position and angle of tilt of the latter were determined. Except where otherwise stated, the subject viewed the two arrows with complete freedom of eye movement and with as much time as he required to make the alignment.

Several series of pairs of targets were used, all the pairs in a series having the same percentage difference in length but different mean length. The mean lengths and target distance were such that the angular subtense at the eye varied from 4° to 0·75°. The fovea subtends an angle of about 1°. With targets of angular subtense 4° the observed tilt was very much less than the theoretical value, that is, less than the value determined from the simple geometrical consideration mentioned in the first paragraph. Reduction in the angular subtense of the targets reduced the discrepancy between the observed and theoretical tilts until the images were entirely foveal, when the difference between the observed and theoretical tilts vanished. The full line on the graph shows, for one observer and for one series of targets, the variations in the observed tilt with the variation of angular subtense of the targets. The percentage size differences in the targets were such as to give a theoretical tilt of 60°. The observer had no detectable eye faults and was considered to have normal vision. Other observers with normal vision produced similar results.



If the targets were large, the eyes of the observer were seen to make continuous scanning movements back and forth along the targets. When these scanning movements were suppressed, by compelling the observer to maintain fixation of a small mark placed at the centre of one of the arrows, the perceptual images ceased to display any stereoscopic qualities and no tilt was observed. Again, in other experiments, small marks were placed beyond each end of one of the arrows and the observer was asked to make voluntary oscillations of the fixation point between the two marks. This artificial extension of the amplitude of scanning caused the observed angle of tilt (shown in the broken line on the graph) to be increased, although the increased tilt was still much smaller than the theoretical value. Both the increase in the angle of tilt under such extended scanning, and the tilts observed for large targets under normal scanning, were found to vary from individual to individual.

It is rather surprising that the graph of the observed tilt against angular subtense is a smooth curve. So far, no explanation for this variation of tilt with increasing peripheral imagery can be offered; but it should be mentioned that the conditions of observation in the experiment are to a certain extent unreal. The objects observed, which are the images of the targets in the stereoscope mirrors, lie in the observer's frontal plane. Hence, the variations in vergence during scanning are very much smaller than the variations which occur when an object tilted out of the subject's frontal plane is observed in normal vision.

From the results, however, it is fairly clear that two separate processes are involved in our perception of space. If we observe limited fields the images of which are formed entirely on the fovea, our stereoscopic appreciation of space is governed entirely by retinal image disparity. But if the objects are larger —and they usually are in everyday life—the simple geometrical picture breaks down and the stereoscopic effects depend not only on retinal image disparity but also on the extent of field observed. In such extended field vision the experiments appear to show that space perception is achieved largely by the ranging or scanning of the field by the eyes. Such a scanning process can very probably be considered to be one of learning or experience, since extra-foveal spatial perception becomes much more accurate when consciously practised. The differences between observers then arise partly from differences in training but also quite probably from anomalies of various kinds in the binocular visual mechanism.

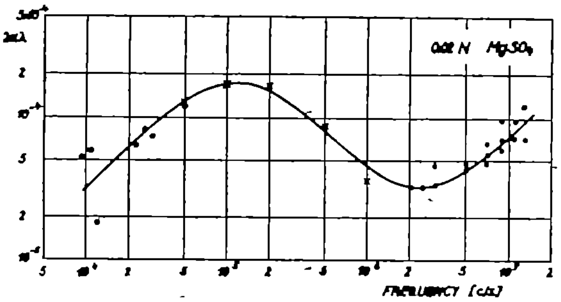
Absorption of Sound in Aqueous Solutions of Electrolytes

A large number of aqueous solutions of electrolytes have been investigated for frequency-, concentration- and temperature-dependence of their absorption of sound in the frequency-range 8 kc./s. to 15 Mc./s. It has been found that all uni-univalent salts investigated have no measurable sound absorption, that is, their excess absorption in concentrations up to 1 mole per litre is less than 10 per cent of the absorption of pure water. This proved to be the case also for a number of bi-univalent salts, except for high concentrations of sodium sulphate and magnesium chloride.



Absorption coefficient of a 0·02 N magnesium sulphate solution × wave-length ($2\alpha.\lambda$) vs. frequency

○, Measured by resonance method; ×, measured by reverberation method; ●, measured in progressive waves

The bi-bivalent sulphates examined (magnesium, manganese, copper, zinc, cobalt and nickel salts), on the contrary, showed very great absorption, which, from the slope of the frequency response, must be due to a relaxation process[1]. For example, the frequency response of the absorption of a 0·02 N magnesium sulphate solution is given in the accompanying graph, where $2\alpha.\lambda$ is plotted as a function of frequency. These parameters give a typical relaxation curve with a maximum at 120 kc./s. Other sulphates show similar curves, the relaxation frequencies of which are somewhat higher (for example, manganese, copper, zinc and cobalt sulphates), or lower (for example, nickel sulphate). The dependence on concentration from 0·002 to 0·2 mole per litre for magnesium sulphate proved to be linear within the limits of accuracy of measurement, that is, there is a constant absorption effect or absorption cross-section per molecule. Although this result is opposite to the expectation of Liebermann[1], who assumed an increase of the absorption cross-section proportional to the square root of the concentration, we believe that the relaxation process must be due to an interaction between the ions similar to that assumed by Liebermann. In favour of this are the changes of absorption observed in mixing different salts. In particular, we found the following rule for mixtures of magnesium sulphate and sodium chloride. The decrease of absorption observed when sodium chloride is added to a magnesium sulphate solution can be explained by the loss of some of the ion-pairs of the magnesium sulphate through interaction with the sodium chloride, which therefore cause no absorption in this frequency-range. The remainder of the magnesium sulphate concentration still effective in absorption is given by:

$$C_{\text{eff}} = [MgSO_4]\,\frac{[MgSO_4]}{[MgSO_4] + f.\,[NaCl]}\,;\quad f = 1/5.$$

The factor $f = 1/5$ can be explained by the difference in interaction between 2-2- and 2-1-valent pairs of ions.

The further increase of absorption[2] above 5 Mc./s. is also remarkable. From its frequency response, it seems to be due to another relaxation process, caused by a change in the hydration shells of the reacting ions. The dependence of frequency response and the amount of absorption on concentration and temperature are in accord with this view.

The measurements were made with different methods in successive frequency-ranges, since any one method is only applicable in a limited frequency-range of about 1 decade.

In the range 8–50 kc./s., the absorption of the solution was determined from the decay constant of a single natural vibration of the solution in a spherical glass vessel with thin walls[3]. The losses of the walls were eliminated by comparison with the decay constant of pure water, measured at the same natural frequency. The absorption of pure water was assumed to be given by

$$2\alpha/f^2 = 50 \times 10^{-17}\ \text{cm.}^{-1}\text{sec.}^2,$$

the value which is obtained at higher frequencies.

In the range from 50 kc./s. to 1 Mc./s., a statistical reverberation method according to Meyer and Skudrzyk[4] has been applied, using a 100-litre aluminium vessel. With this method a mean value of the decay constants of many natural vibrations is measured, within a band-width of ± 10 kc./s. The losses at the walls here, too, are eliminated by comparison with determinations using pure water.

In the frequency-range 3–15 Mc./s., the absorption was determined from the difference of level of the sound intensity in a plane progressive wave at two different distances from the source. This difference was obtained by photometrical comparison of the diffraction loss of the zero-order light of two beams of light crossing the sound field. The absorption determined for pure water by this method differs up to 10 per cent from the above-mentioned value. The excess absorption of magnesium sulphate as given in the graph is only of the same magnitude as the absorption of pure water in this frequency-range.

FORTHCOMING EVENTS

Wednesday, August 29—Saturday, September 8

EIGHTEENTH NATIONAL RADIO AND TELEVISION EXHIBITION (at Earls Court, London, S.W.5).

Thursday, August 30—Thursday, September 13

ENGINEERING, MARINE AND WELDING EXHIBITION (at Olympia, Hammersmith Road, London, W.14).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT TEACHER IN THE DEPARTMENT OF PHARMACY AND BIOLOGY—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (September 1).

DEMONSTRATOR (temporary) IN BOTANY—The Secretary and Registrar, University College of North Wales, Bangor (September 1).

STATISTICIANS (with a university degree in statistics or in mathematics, economics or other appropriate main subject, combined with statistics, with at least second-class honours or equivalent) in the Board of Trade, London—The London Appointments Office, Ministry of Labour and National Service, 1–6 Tavistock Square, London, W.C.1, quoting JN.120 (September 6).

CIVIL ENGINEER on the staff of the Chief Mechanical and Electrical Engineer in the Production Department at London headquarters—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed TT/365 (September 8).

ENGINEERS I at a Ministry of Supply establishment in London: (Ref. C.486/51A) to be responsible for planning and production, including preparation of plant layout, or either fuses, igniters, primers and all ancillaries for all types of ammunition, (Ref. C.487/51A) for small arms ammunition, including filling, (Ref. C.488/51A) with experience in methods of planning, sufficient to control a section responsible for the compilation and critical analysis of production and repair requirements for airframes, engines and associate equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 8).

ENGINEERS, MATHEMATICIANS or PHYSICISTS (Senior Scientific Officer grade) at a Ministry of Supply Experimental Aircraft Establishment in southern England, for research work in connexion with aircraft flight testing—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.221/51A (September 8).

LECTURER IN PHYSIOLOGY, and an ASSISTANT IN MATHEMATICS—The Secretary, The University, Edinburgh (September 8).

PHYSICISTS and ENGINEERS (Experimental Officer grade) at the Atomic Energy Research Establishment, Harwell, to take charge of the Electrical Standards Laboratory—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.234/51A (September 8).

PSYCHOLOGICAL TESTERS IN H.M. Prison and Borstal Service at Birmingham, Bristol, Durham, Liverpool and London—The Establishment Officer (E.84/4/7), Prison Commission, Dean Ryle Street, London, S.W.1 (September 8).

SCIENTIFIC OFFICERS or SENIOR SCIENTIFIC OFFICERS at the National Physical Laboratory for work in physics, mechanical engineering, metallurgy, radio and naval architecture—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.222/51A (September 8).

SENIOR ENGINEER, DESIGN SECTION, Dominion Physical Laboratory, Department of Scientific and Industrial Research, Lower Hutt, New Zealand—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (September 10).

SENIOR ASSISTANTS (Scientific): CHEMISTS experienced in analytical work, for the testing and analysis of soils, feeding-stuffs, fertilizers, milk, etc., BACTERIOLOGISTS experienced in laboratory routine, BIOLOGISTS experienced in the routine of a general biological laboratory, and specialized in either plant pathology or entomology and microscopy, BIOCHEMIST with knowledge of hygiene and pathology and ability to assist in teaching in these fields, BIOCHEMIST with sound knowledge and experience in nutritional work, CHEMICAL ENGINEER for supervisory duties, ELECTRONICS ENGINEER with specialized knowledge of Post Office relays—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4064/51LA (September 13).

ASSISTANT LECTURER or LECTURER IN CIVIL ENGINEERING at Gordon Memorial College, Khartoum—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 15).

LECTURER IN AGRICULTURAL BOTANY—The Registrar, King's College, Newcastle-upon-Tyne (September 15).

LECTURER IN MINERAL DRESSING AND ASSAYING in the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 15).

PRINCIPAL RESEARCH OFFICER or SENIOR RESEARCH OFFICER (Ref. No 3510), to lead a scientific unit that will include a geologist, geomorphologist, pedologist and ecologist, to carry out surveys in Papua and New Guinea, organize the assembly of existing information and co-ordinate the work of the several specialists in the unit, a SENIOR RESEARCH OFFICER or RESEARCH OFFICER (Ecologist) (Ref. No. 3511), to serve as plant ecologist to the unit, and a SENIOR RESEARCH OFFICER or RESEARCH OFFICER (Geomorphologist) (Ref. No. 3512), to make special studies in the field of geomorphology, and act in general co-ordination with the geologist and pedologist—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 15).

SCIENTISTS, Grade II (with good honours degrees or equivalent qualifications in science or engineering, and some previous research experience) at London headquarters, to assist in the formulation and progressing of research programmes—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed TT/366 (September 15).

SOIL CONSERVATION OFFICERS in the Department of Conservation and Extension, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (September 15).

ELECTRONIC ENGINEERS in Ministry of Supply establishments in southern England, for the design of radio and/or radar components, equipment and installations (including aerials) and engineering of prototypes for production—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.359/51A (September 17).

FORESTRY INSPECTOR (Grade III, established), and a FORESTER Grade III, unestablished)—The Secretary, Civil Service Commission, (5 Upper O'Connell Street, Dublin (September 20).

CIVIL and MECHANICAL ENGINEERS at Ministry of Supply research and development establishments in London, Glasgow, Farnborough, Christchurch, Salisbury and St. Helens, for design, development and installation work in the structural and plant engineering fields—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.485/51A (September 22).

ENGINEER I at a Ministry of Supply establishment at Salisbury. to be responsible for the design, erection, calibration and final testing of chemical plants—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.228/51A (September 22).

ENGINEERS I in Ministry of Supply establishments in London and the Provinces for (*a*) factory production management on gun carriages and tanks, ammunition, small arms, filling; (*b*) development of maintenance and services work in filling and explosives factories, (*c*) various Headquarters posts on production planning and progressing, or on maintenance, services, plant installation, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.472/51A (September 22)

ELECTRONIC ENGINEERS in the Ministry of Supply, to work near London or at provincial stations on the development and design of electrically operated systems for a variety of applications including weapons, telecommunications and radar equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.134/51A (September 24).

LECTURER IN DAIRY HUSBANDRY at Massey Agricultural College (University of New Zealand), Palmerston North—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 25)

PHARMACOLOGIST to the Alfred Hospital, Prahran, Melbourne—The Agent General for Victoria, Victoria House, Melbourne Place, Strand, London, W.C.2 (September 29).

LECTURER IN NUTRITION at the School of Home Science, University of Otago, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 30).

PROFESSOR OF ANATOMY—The Registrar, University College, Cathay's Park. Cardiff (September 30).

PROFESSIONAL ENGINEERS, General Service Class (Main and Senior grades), in Government Departments—The Secretary, Civil Service Commission, Trinidad House, Old Burlington Street, London, W.1, quoting S 86/51 (October 1).

DIRECTOR OF THE GEOLOGICAL SURVEY, Department of Industry and Commerce, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (October 18).

ASSISTANT BIOCHEMIST in the Department of Pathology—The Secretary, Bolton and District Hospital Management Committee, Royal Infirmary, Bolton.

ASSISTANT LECTURER IN PHYSICS—The Registrar, The University, Nottingham.

BIOCHEMIST, to direct and carry out work in intermediary metabolism and in problems of enzyme inhibition—Box No. 23, Ottawa, Ontario, Canada, quoting Competition No. G-18.

B.L.M.R.A. FELLOWSHIP, for research in the Leather Industries Department, University of Leeds under the direction of Prof D Burton, and a JUNIOR SCIENTIFIC OFFICER (with a good honours degree and, preferably, some knowledge of chemical engineering) to work in the chemical engineering section—The Director of Research, British Leather Manufacturers' Research Association. Milton Park, Egham, Surrey.

CHEMISTS or ENGINEERS (3), to visit members' works in all parts of the British Isles—The Director, British Launderers' Research Association Laboratories, Hill View Gardens, London, N.W.4.

HONOURS GRADUATE IN PHYSICS, to teach physics up to general B Sc. standard, together with some mathematics up to Inter.B.Sc. standard—The Principal, Gloucester Technical College, Brunswick Road, Gloucester.

PHYSICIST (honours degree in physics and some research experience essential) to take charge of the South Wales Laboratory in Swansea—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1.

POSTGRADUATE ASSISTANT in connexion with work on Nuclear Physics—The Clerk, Birkbeck College, Breams Buildings, London, E.C.4.

PROFESSOR AND HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING (Heavy), Indian Institute of Technology, Kharghpur—The Ministry of Labour and National Service, Technical and Scientific Register (A.8.12), York House, Kingsway, London, W.C.2, quoting A.12/UNH/150/51.

PROFESSORS (2, one of whom should have special qualifications in applied thermodynamics) IN THE FACULTY OF MECHANICAL ENGINEERING, at the Technion (Institute of Technology), Haifa, Israel—The Secretary, The Technion Society of Great Britain, 13 Mansfield Street, London, W.1.

Senior Lecturer, and a Lecturer, in Physics, at the Bradford Technical College—The Director of Education, Town Hall, Bradford.

Senior Scientific Officers and Scientific Officers in various Government departments and covering a wide range of scientific research and development in most of the major fields of fundamental and applied science—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting No. 3399.

Teacher of Pharmacology (of professorial grade), and a Pharmaceutical Chemist, at the Hardinge Medical College, New Delhi—The Secretary (Division 5A), Ministry of Health, Savile Row, London, W.1.

VOLUNTARY BODIES AND THE SUPPORT OF RESEARCH

IN the admirable record of beneficent activity which characterizes the successive annual reports of the Nuffield Foundation, the discrimination and care with which the Foundation selects the projects for assistance is obvious. It can fairly be claimed that, over the six years of its activity, the Foundation has consistently fostered the growing-points of science, and especially of the biological and social sciences, in exactly the way that Lord Beveridge recognized as so important in his report on voluntary action Much has, in fact, been done already by the Foundation to assist in keeping the advancing front of science in balance and ironing out the unevenness that sometimes hinders progress or contact between two or more fields.

One of the most interesting features of the Foundation's reports has always been the discussion of general policy and of the principles by which the trustees have sought to determine that policy. The sixth report[*] raises one matter of outstanding interest, especially to the scientific community, and its significance is strikingly emphasized by passages in two other recent reports from similar bodies—the Pilgrim Trust and the United Kingdom Carnegie Trust—as well as by one passage in the third report from the Committee of Public Accounts for the Session 1950–51.

The report welcomes the appointment last year by the Prime Minister of a committee under the chairmanship of Lord Nathan "to consider and report on the changes in the law and practice (except as regards taxation) relating to charitable trusts in England and Wales which would be necessary to enable the maximum benefit to the community to be derived from them"; it believes that it is in the public interest that the uses to which such funds can properly be put should be reviewed, and if necessary reformed. The report then emphasizes the need for flexibility rather than administrative convenience; while the ancient law of charities may require revision to meet modern needs, it is against too narrow and inelastic a definition of the objects of individual charitable bequests that precautions are required. Social advance would be impeded if charitable trusts were rigorously debarred from venturing into territories where statutory authorities are now enabled to make general social provision. As Lord Beveridge pointed out, new methods of meeting the changing needs of a developing society have in the past largely resulted from the prospecting of voluntary bodies, followed by central and local authorities consolidating and extending.

Any overlapping of effort or administrative untidiness is more than offset by the greater opportunity to experiment which such a relation between voluntary or private and public action affords, and the Nuffield Foundation rightly stresses the importance of such freedom to experiment, to move swiftly to the initiation or support of projects which promise to be of benefit to mankind. Some such projects might never be explored if it was always necessary to wait until public authority was convinced of the need, or could commit adequate resources to meet the need. The new feature in the situation to which the Foundation directs attention in this report is the possibility that bodies like itself may be faced with a less adventurous but more difficult choice of objectives. They may be required to turn from initiating to sustaining projects which hitherto have been sustained by the community.

---

[*] Nuffield Foundation. Report for the Year ending 31 March 1951. Pp. 113. (London: Nuffield Foundation, 1951.)

The suggestion in the report that there may be a contraction of Government spending upon some social and intellectual purposes is not to be dismissed lightly. Though the nominal total of State support for learning and research has not as yet been decreased in the official estimates for the immediate future, the costs and materials of scholarship and research are steadily mounting in price. The real values of Government subvention, and of permanent endowments, for research are therefore bound to decrease. Moreover, the proposal in the White Paper on broadcasting policy to mulct the British Broadcasting Corporation of 15 per cent of the net revenue from wireless licences is not to be dismissed as merely an example of Treasury small-mindedness or dishonesty. If revenue contributed specifically for this purpose is to be raided thus as a contribution to rearmament, what is to stop the contributions of industry to the research associations or the revenue of the universities being raided on similar grounds ?

The speciousness of such an argument would be disturbing at any time, and in the present circumstances there will be profound disquiet in all circles interested in the furtherance of scientific and industrial research until the Government abandons so dubious a proposal. Nor is the disquiet diminished by the reference to the expenditure of the Department of Scientific and Industrial Research on the research associations contained in the report of the Select Committee on Public Accounts already noted. Commenting on the way in which the Industrial Grants Committee of the Advisory Council for Scientific and Industrial Research considers applications for grants and calculates the amount of any grant *pro rata* on the contribution made by the industry, the Select Committee expresses the opinion that *pro rata* grants are not best calculated to promote efficient economy, and may result in grants from public funds for research directly benefiting industries well able to meet the cost from their own resources.

The implications of this apparently reasonable argument deserve more attention than they have yet received. It is improbable that the Advisory Council, which is already informed of the details of research undertaken or proposed by each association, would be involved in any serious inquisition by the adoption of the Select Committee's recommendation for inquiry as to the financial position of the industry concerned. Leaving aside, however, the practical difficulty of assessing the capacity of an industry to finance research, the Committee's proposal for what is in effect a 'means test' shows a misconception of the whole purpose of co-operative research.

The case for State assistance of the research associations rests fundamentally on the belief that industrial research of this character is of direct advantage to the community as a whole, and not merely to the particular industry concerned. The economic well-being of the nation depends, in fact, on a progressive industry awake to all the opportunities which scientific and technical advance afford, and ready to turn them to advantage in the improvement of existing, or the development of new, products and processes. Part of the function of the research associations is indeed not so much the acquisition of new knowledge as the more effective and wider utilization of existing knowledge.

Accordingly, the important and fundamental question is not what should be the magnitude of any grant from the State, but whether the proposed programme of research is directed at the right targets. This is a question which is only with difficulty assessed from outside, and even from within an industry it may require a term of years to show the wisdom or otherwise of choosing the targets and activities adopted. Moreover, where part of the function of a research association is to educate the industry it serves and to seek to encourage the prosecution of research not only in the association's own laboratories but also in the industry at large, it would manifestly be a retrograde step to determine the research association's budget by the capacity of the industry to pay rather than, as at present, by the willingness of the industry to participate in co-operative research.

On the Select Committee's own showing, the Industrial Grants Committee of the Advisory Council is asking the right questions and putting first things first. Given that it is in the national interest to encourage as widely as possible the prosecution of industrial research, it would be a step backwards and false economy to change the emphasis or the arrangements and practice that have proved their value over more than three decades. What is essential is not the kind of scrutiny suggested by the Select Committee but, from time to time, a much more fundamental scrutiny of the whole structure and functioning of the research association movement in the light of changing conditions, to make sure that the nation and industry continue to get full value for their expenditure and that resources of money, materials and man-power are not diverted into this channel when they could more profitably be expended in other ways.

The outlook indicated in the Select Committee's report and in the Government's memorandum on the report of the Broadcasting Committee thus increases the concern already entertained, as suggested in the Nuffield Foundation's report, as to the possibility of rising costs compelling the Government to curtail scientific research. There has been no proposal as yet to cut the estimates for scientific research; but the situation fully warrants the suggestion that some statement of the Government's intentions should be made at an early date by the Lord President of the Council. Meanwhile, common prudence suggests that it would be wise for the Department of Scientific and Industrial Research, and also other bodies, including the universities, to scrutinize carefully their research programmes and ancillary activities with the view of eliminating any items for which a convincing case cannot be argued, and making sure that there is no waste of either man-power or materials.

Whether or not the pessimism suggested by the Government's memorandum and the report of the Committee of Public Accounts is justified, a realistic approach to research budgeting is undoubtedly required. The Nuffield Foundation's immediate concern is that it may be required in consequence of Government economy to choose between sustaining minimum academic activities thereby endangered and, on the other hand, encouraging novel proposals which may in such circumstances find it even more difficult to command a hearing. The danger of any real drying-up of enterprise in the field of research is unlikely to be great. What is endangered is the support of those growing points which from their nature are bound at first to be speculative and often illusory, but which nevertheless when genuine make decisive contributions to human welfare and the advancement of learning.

The present report of the Nuffield Foundation should therefore be read carefully by all who realize the importance under present conditions of preserving independent institutions which are free to experiment and to test the value of new projects in a way that no Government institution could readily do, even if free from the inhibitions already indicated. Both in the introduction to the whole report and in that to the section dealing with fundamental research, and again in that dealing with research into practical problems, it is apparent how great is the opportunity which still confronts the Foundation and with what care the Foundation determines its policy; and valuable as is its support of fundamental biological studies, that given to sociology may well be even more important at the present time. It is perhaps the most hopeful means available to us of averting that very real danger to which the weaker sociological departments in the universities might be exposed in competition with the stronger and more firmly established departments of physical science, in the absence of earmarked grants.

The Carnegie United Kingdom Trust*, like the Nuffield Foundation, is required to promote pioneer efforts for the advancement of social welfare, but in view of its smaller resources, which are only a quarter of those of the Nuffield Foundation, the Trust has concentrated its resources on objects which can be promoted significantly by a relatively small outlay and has consistently withdrawn its support as soon as success or failure has been conclusively demonstrated. When that stage is reached, failures, as, for example, the Bureau of Current Affairs, are abandoned, and successful ventures are transferred to public or voluntary bodies, while the Trust passes to fresh ventures. The most important single enterprise to which the Trustees have set their hands, for example, is the development of library services, on which since 1913 they have spent more than one and a half million pounds. This work will now continue without further financial assistance from the Trustees, and the current report for 1950 records that in this period annual expenditure by public library authorities in the United Kingdom increased from £800,000 in 1911 to £6,700,000 in 1948.

Other instances are cited in this report of the way in which modest experiments by the Trust have developed into institutions with a permanent place in the social structure of Great Britain and now in receipt of an Exchequer grant. So many of the old projects have now for such reasons been dropped that the total sums already earmarked for dispensation in the new quinquennium 1951–55, including £40,000 for the development of museum services, leave a considerable margin, either for the introduction of new schemes of development on a large scale or for financing single pieces of pioneer or experimental work likely to prove of national importance. Some four-fifths of the Trust's budget is, in fact, available for such purpose, and it would seem that the Trustees are now faced with a choice between assisting innovations in social welfare now increasingly in the hands of public authorities, or assisting voluntary enterprises even if they are not strictly of the pioneering type.

The picture displayed by the Carnegie Trust calls for reflexion as much as does that of the Nuffield Foundation's report. Both vindicate abundantly the value of the independent trust in social pioneering and research and the room for such voluntary work to-day. It should be no less clear that the limits of such enterprise and their freedom to experiment will be seriously circumscribed if they are only able to operate in association with public authorities, to which they would of necessity be subordinate. Definition or delineation of function is not easy; but it is clear that much would be lost if the promotion of social advance or of research in general were entrusted exclusively to the State. Both State institutions and voluntary associations have their part to play, and the latter are the repositories of the initiative and freedom to experiment which are always the sources of real advance in science or other human activities. There could be no clearer warning of the need for some such independent institutions, to preserve the atmosphere in which research and the pursuit of learning or the service of mankind are most fruitfully pursued, than the intimation of the narrowness of view and short-sightedness which are liable to cramp official action or policy that is given in the two official papers already mentioned.

EVOLUTIONARY THEORY

Animal Evolution

A Study of Recent Views of its Causes. By G. S. Carter. Pp. xv+368. (London: Sidgwick and Jackson, Ltd., 1951.) 30s. net.

"ANIMAL Evolution", by Dr. G. S. Carter, is an unusually well-balanced account of the present state of evolutionary theory written with the student reading zoology at a university chiefly in mind. The discussion is restricted to animals and largely to those in which the reproduction is bisexual. There are two equal parts: (1) the basis of biological fact; (2) the theory of evolution.

---

* Carnegie United Kingdom Trust. Thirty-seventh Annual Report. Pp. viii 49. (Dunfermline: Carnegie United Kingdom Trust, 1950.)

In the opening chapter, "The Palæontological Data", the author distinguishes the characteristic patterns of evolution at three levels: micro-, macro- and mega-evolution. In "The Genetical Background", special attention is devoted to the physiology of the gene after a brief presentation of the basic principles of chromosomal organization and of the phenomena of mutation. In "The Species in Zoology", the traditional concept of the systematist—the species as a kind of animal, distinguished from others by at least one consistent character—is contrasted with the species of the naturalist and of the geneticist: a chain of interbreeding communities. The latter is preferred; but it is noted that there is usually convergence toward the same conclusions with respect to living forms. The genetics of differences within and between species is gone into briefly. In Chapter 4, "Intraspecific Categories", it is pointed out that even in common species the occupation of the range is in most cases highly spotty and that this is very important to evolution. The convenient term 'deme' (of Gilmour and Gregor) is used for these partially isolated, and often rather small, communities. The cline and the subspecies are also discussed. In Chapter 5, on "Competition, Isolation and Natural Selection", the author goes at considerable length into the conclusions of statistical genetics as well as into experimental and observational evidence on the success of selection within and between species.

The conclusions of Part 1 are applied systematically to the interpretation of "Micro-evolution" in Chapter 6 and of "Macro- and Mega-evolution" in Chapter 7, continued under the heads "Pre-adaptation", "Evolutionary Trends", "Evolution and the Life-history" and "Rates of Evolution" in the remaining chapters.

In his final conclusions, the author dwells especially on the concept of evolution as a "change in the animal's whole life, in its ecology, habits and behaviour as well as in the organization of its body", and as a process concerned with harmonious genotypes rather than separate genes. He also emphasizes that evolution in bisexual forms is something that happens to populations, not individuals or lineages, and again stresses the importance of the deme as the elementary unit of population.

The reviewer is especially glad to note the emphasis on the genotype and on the deme. He ventures, however, to suggest that these may be tied much more closely together than is done here. In a species with exclusive bisexual reproduction there can be no selection by genotype (beyond a mere summation of separate processes, relating to the average differential effects of the genes) except on the basis of interdeme selection. Such a process occurs wherever the demes are differentiated, in partial isolation, and those with superior adaptation to common environmental or social conditions can contribute more than their share to the next generation by infiltration of neighbouring, less adaptive portions of the species. Random drift of any sort is of more than trivial significance only in conjunction with local selection; but a joint process ensures the differentiation of the genetic complexes of demes, even under common conditions, and thus provides material for interdeme selection.

While Dr. Carter approaches evolution primarily from the point of view of ecology, his conclusions are, I believe, quite in harmony with those of most geneticists on such matters as the roles of micro- and macro-mutation and on the various topics indicated by the chapter titles in Part 2. The greatest gap that he finds in the genetic evidence, that might perhaps be expected to be available, is the absence of known mutations that go beyond mere changes in proportions of parts or replications (including homœotic ones) in such a way as to give a basis for "the appearance in the course of evolution of novelties in the organization of the body where there was no previous differentiation to be modified into them".

SEWALL WRIGHT

'THE EXCELLENT MR. RAY'

John Ray

A Bibliography. By Dr. Geoffrey Keynes. Pp. xv+163+4 plates. (London: Faber and Faber, Ltd., 1951.) 50*s*. net.

DR. KEYNES acknowledges in the first sentence of his preface that it was Canon Raven's biography of John Ray, published in 1943, that first opened his eyes to "the extraordinary qualities and endearing character of that remarkable man" and induced him to provide a supplement to Raven's book in the form of a "full-scale bibliography" of Ray's works. This he has done with the attention to detail which we should expect from a vice-president of the Bibliographical Society. Each of Ray's books is fully described, many of them with a photographic facsimile of the title-page, and all with a collation of sheet-signatures and an enumeration of the contents by pages, followed by a list of the copies known to survive, with an indication of the libraries in which they are preserved. With one exception, these libraries are in Britain, and most of them are the great national and university or college libraries. In these categories, however, there are one or two curious and unexplained omissions. For example, while the Universities of Aberdeen, Glasgow and Edinburgh are duly entered, there is no mention of the senior Scottish University, that of St. Andrews, although there is in one of its libraries at least one volume that would have been worthy of record. The abbreviation *YML* occurs in a number of places in the text; but is not included in the "List of Abbreviations" which follows the preface. It may be worth pointing out, therefore, that it is explained on p. 154 in the "Index of Copies Recorded" as referring to "Yale Medical Library".

The author expresses, in his preface, the hope that he has "brought forward evidence in a bibliographical dress" of Ray's "modesty, his loyalty and his integrity". As a matter of fact it is not immediately obvious that he has added a great deal to what we already know on these topics from Canon Raven's "Life". We do, however, learn that Ray, excellent old-fashioned scholar that he was, went to the trouble (and perhaps expense) of reprinting a title-page to rectify two, not very conspicuous, errors in Latinity and that the ignorance, or carelessness, of a bookbinder has left at least two of the surviving copies with the original, incorrect, page, several of the others with the corrected one, and one copy with both.

The volume is finely produced. The printing is what we expect from the Oxford University Press at its best. It is printed on grey paper, and, since the author is a distinguished surgeon as well as a bibliographer, one may assume that he is satisfied that this will avoid eye-strain. Whatever may be the case in conditions of full illumination, this may perhaps not be so in the dim lighting to which we are becoming accustomed in these days of electricity cuts.

Finally, in the "Note on the Portraits of Ray" on p. 151 it is stated that the portrait in the British Museum (Natural History), attributed to Mary Beale, "bears no resemblance to Ray and is difficult to accept as a portrait of him". The present writer, having shared a room with this portrait daily for some ten years, does not find it so hard to believe that it really represents the man whose name is inscribed on it.

W. T. CALMAN

RELATIVITY FOR EXPERIMENTAL PHYSICISTS

Weltsystem, Weltäther und die Relativitätstheorie

Eine Einführung fur experimentelle Naturwissenschaftler. Von Prof. Dr. Karl Jellinek. Pp. xv+450. (Basel: Wepf and Co., 1949.) 45 Swiss francs.

THERE is no lack of books on Einstein's theory of relativity, but Prof. K. Jellinek, the author of a five-volume work on physical chemistry and formerly head of the Physical Chemistry Institute of the Technical High School at Danzig, believes that none before his own is really suitable for experimental physicists. It is just as important to-day as when relativity theory first appeared that those engaged in experimental research in physics should have sound ideas about the fundamental concepts of space, time, motion and mass; yet most existing books leave them in a muddle, destroying their old ideas without giving them anything tangible in exchange. The books written for mathematical physicists are often excellent in their own way, but an abstract system of differential equations is rather unsatisfying to the experimentalists, who wonder if this is all they are offered to replace their former belief in a physical ether. The books written for a popular audience avoid abstract mathematics; but they are often superficial, revelling in paradoxes and sensational pronouncements, so that they are more suitable for seekers of entertainment than for seekers of truth.

A third kind of book is needed, which, without sacrificing accuracy, stresses the concrete rather than the abstract and the positive rather than the negative. For example, after giving the usual rejection of Newton's concept of absolute space, Prof. Jellinek asserts emphatically that relativity physics still admits of a universal frame of reference. This assertion is supported by quotations from Einstein, Kopff, Thirring, Beck, Eddington, Tolman and Robertson. The author also believes that relativity physics still admits of belief in a universal ether, with three essential properties. It is, as a whole, at rest relative to the universal frame of reference; it propagates the phenomena of light, electro-magnetism, gravitation, and inertia with constant velocity relative to that frame, irrespective of the velocity of the source; all material bodies, such as electrons, positrons, neutrons, protons, atoms, molecules, and the heavenly bodies represent certain modifications of the ether, through which they move freely. These opinions are supported by quotations from Einstein, Eddington and Weyl. The author also holds some other beliefs about the ether (pp. 23–26), which he recognizes as not generally accepted, but he points out that these can be rejected without affecting the arguments of the rest of the book. As for the space-time continuum, he believes, unlike Eddington, that this should be considered merely as a useful mathematical device and not as a physical reality like the universal frame of reference and the ether, which give a firm basis for clearing away all the paradoxes usually associated with relativity.

The topics mentioned above are dealt with in the preface and two short chapters. A long third chapter (pp. 27–142) deals with the special theory of relativity, on much the usual lines except for the stress on optical experiments and a long discussion of the clock paradox. The fourth chapter (pp. 143–166) gives a brief introduction to tensors. Here and elsewhere the only knowledge that the student is assumed to possess is very small, merely the elements of calculus and of mathematical physics. A long fifth chapter (pp. 167–307) deals with Einstein's theory of gravitation rather differently from usual; to reduce the difficulty, the simplest ideas of the theory are treated at length, before passing on to the important but more difficult aspects. A more general formulation of this theory is given in a short sixth chapter (pp. 308–331). The seventh chapter (pp. 332–381) returns to the questions of a universal frame and ether, and investigates them for three statical cosmological systems, while the eighth chapter (pp. 382–404) investigates them for a non-statical and expanding universe. The ninth chapter (pp. 405–412) gives a brief account of E. A. Milne's kinematical relativity. Unfortunately, Einstein's latest theory was not available when the book was published. In conclusion, there are several mathematical appendixes, a bibliography, and indexes of authors and of subject-matter.

It would be presumptuous for me to pronounce on the soundness of the controversial parts of this book, but it can be safely asserted that they will be found of great interest. It is a pity that the high price may prevent many from examining the book for themselves.

H. T. H. PIAGGIO

BRITISH ORCHIDS

Wild Orchids of Britain

With a Key to the Species. By V. S. Summerhayes. (New Naturalist Series.) Pp. xvii+366+72 plates. (London and Glasgow: Wm. Collins, Sons and Co., Ltd., 1951.) 21s. net.

NO group of British plants has attracted more attention than our native orchids. In spite of this, prior to the appearance of Mr. V. S. Summerhayes's book, no real authoritative work on the subject existed. Now we have a comprehensive book dealing with the plants from every point of view, their classification, natural history, ecology and biogeography all receiving adequate attention. Moreover, the volume is well illustrated by a series of colour and other photographs, text figures and maps.

Just after the First World War, British orchids became the objects of much intense research. Taking cognizance of this work, but neglecting such trivialities as *Orchis francis-drucei*, and reducing *O. hebridensis* to its proper level as a subspecies of *O. fuchsii*, Mr. Summerhayes has produced on pp. 107–8 a thoroughly trustworthy list of species. Each of the species admitted to this list is discussed so fully that one wonders at the author's skill in getting the essential facts into so small a space. Careful scrutiny of his descriptions only serves to confirm their general reliability. This, of course, does not imply that no minor blemishes exist, for such do occur, especially among the dactylorchids.

In the first place, we feel sure that the orchid figured on Plate 38*b* has little to do with the *O. traunsteinerioides* forms recorded from Wicklow and Durham; the differences between the two sets of plants are too strongly marked for that. Furthermore, we doubt the relationship suggested between the Wicklow and Durham plants and true *O. traunsteineri*, of which we possess authentic Irish specimens. We do, however, recognize their obvious affinity with *O. majalis*. As for the origin postulated on p. 295 for *O. traunsteinerioides*, it seems to be impossible for several cogent reasons: the chromosome numbers of the putative parents do not fit, nor, in the case of the Durham plant, do its associates and characters.

In respect of *O. purpurella*, certain pronouncements are made which cannot be harmonized with fact. It is asserted to be the latest flowering of the marsh orchids, and the month of its appearance is given as July. Here, in North Durham, it is the earliest of all. In 1950, a late season, masses of inflorescences were visible on May 29; even this season, on May 12, the flowering spikes were well advanced. Much the same holds true in the Inner and Outer Hebrides, where the flowering of *O. purpurella* is at its height during the last week in May, just ahead of *O. latifolia* and *O. occidentalis*.

Similarly, we cannot understand the remarks concerning the anthesis of *O. fuchsii* and *O. ericetorum* made on p. 272, where we are informed that in the Hebrides the former may precede the latter. According to our observations, made over a period of years, Hebridean *O. ericetorum*, even high up the mountain-sides, commences to flower in the middle of May with *O. fuchsii* ssp. *hebridensis* following about June 15. Thus in 1950, in Lewis, Harris, South Uist and Eriskay, although there was some overlap in July, *O. ericetorum* had quite disappeared when *O. fuchsii* was at its best.

The sections devoted to ecology and biogeography now come up for comment. Concerning the former, we have nothing but praise. However, in the case of the biogeography, the accounts should be received with some measure of caution. On p. 69 the pronouncement that the Ice Age occurred 10,000–100,000 years ago is incorrect. Had the latter date been given as 600,000 years ago, we should have had a much closer approximation to the truth. Again, Mr. Summerhayes is inclined to emphasize older conceptions about the history of our flora and fauna. He seems to be unaware that recent investigations have pointed strongly to the possibility that a not inconsiderable portion of our biota migrated to the British area during the last Interglacial Period, or even during favourable interstadial phases in the Upper Pleistocene glaciation. Such contingents, forced westward to suitable refugia when more rigorous conditions returned, and released finally as the glaciers waned, may well be responsible for some of the distributional anomalies so puzzling to plant geographers.

As an appendix we have an excellent and workable key to the species described, followed by a useful glossary, a bibliography and a series of distributional maps. The latter follow the usual practice of blackening the whole of a vice-county when only a single station is concerned. For example, although *Gymnadenia conopsea* and *Anacamptis pyramidalis* are confined in the Outer Hebrides to the small Isle o Fuday, the whole of v.c. 110 is blackened; such procedure may easily vitiate serious phytogeographical researches.

Botanists owe a debt of gratitude to Mr. Summerhayes for producing such an excellent book, and w unhesitatingly recommend it to all interested i British orchids.

J. W. Heslop Harrison

INSECTS AND HYGIENE IN BRITAIN

Insects and Hygiene

The Biology and Control of Insect Pests of Medica and Domestic Importance in Britain. By Dr. Jame Busvine. Pp. xiv+482. (London: Methuen and Co., Ltd., 1951.) 30s. net.

INSECTS do not play a major part in the transmission of human disease in Great Britain, and the damage which they do to stored foods, to clothing, to the structural timbers of buildings, or to furniture is on the whole insidious, and although in the aggregate it is extensive enough, much of it passes almost unnoticed. But as every applied entomologist, every medical officer of health and, indeed, every housewife knows there are a great many troublesome insects in our midst and it is not always easy to obtain the information about them that is necessary for their effective control. Dr. Busvine has produced a truly scientific and very practical treatise on this diverse collection of insects. He has made the attempt of setting out within a single volume the general principles of pure entomology—systematics, anatomy, physiology and ecology, the general principles of applied entomology, and the practical details for the diagnosis and treatment of every pest problem in the home or in the warehouse, in foodstuffs, in timber or on the body. Many of the topics are necessarily treated in a brief and superficial style. But on the whole the author has succeeded in maintaining an admirable balance in the treatment that he gives to all sides of the subject.

In these days when new synthetic insecticides discovered in the past ten years have brought about a revolution in our powers for destroying insects by chemical means, it is sometimes forgotten that most of the insects that trouble the health of man can be controlled by common cleanliness. It was improvements in cleanliness and not insecticides which led to the disappearance of the bed-bug from the houses and the louse from the persons of the upper classes of Britain in the nineteenth century. The flea canno maintain itself in clean houses or clean cinemas; no can the house-fly breed in clean back-yards. It is a notable feature of Dr. Busvine's book that although the sections dealing with insecticides and their uses are particularly good, the biological methods of control—of which domestic hygiene is often the most important—are given full weight.

But the control of insects in human communities is often impossible without the backing of the law In Britain the local authorities have varied legal powers for dealing with insects infesting houses, with verminous persons or with divers nuisances connected with insects. It is useful to find all these matters set out briefly in this book. There are also keys for the identification of most of the insects to which reference is made and an appendix giving chemical details about most of the insecticides now in use.

V. B. Wigglesworth

Laboratory Physics

By J. H. Avery and A. W. K. Ingram. Pp. xi+439. (London: William Heinemann, Ltd., 1950.) 16*s*.

TWO science masters, who obviously have first-hand and wide experience of the difficulties which confront sixth-form and first-year university students when performing the standard physical experiments, have combined to write this excellent text-book. Not only is the student encouraged to make some of the apparatus himself—there are brief instructions on soldering, glass-blowing and drilling, etc., to help him—but also the teacher will find the more precise specification of apparatus than is usual in text-books of this kind most useful in setting up the experiments. Detailed descriptions of nearly two hundred experiments grouped into sections on mechanics and properties of matter, heat, light, sound, magnetism, electricity, and—one which will appeal perhaps more to the technical colleges—electronics are given. The authors state that they were encouraged to include this last section because of the considerable quantity of ex-Government equipment now available to the public. Exercises, problems, a good bibliography, together with an introductory section containing some excellent advice on laboratory notebooks, errors and graphical methods, complete the book.

The diagrams are on the whole clear, but some might with advantage have been larger. Enough theory is given with each experiment to explain the principle and method employed. Natural and forced convection are discussed and the distinction between them carefully emphasized. The authors do not hesitate to point out where difficulties arise, as, for example, in the determination of the internal resistance of a primary cell, and the student is quite correctly referred to the late Sir Cyril Ashford's excellent article on this subject for further information. The 'real is positive' sign convention is used in the light section, but the diagrams are so drawn that the 'new Cartesian' convention can also be applied to them. A regrettable omission is Owen's method for the determination of neutral points by directional loci.

S. Weintroub

Etat actuel de la chimie et de la physique des molécules géantes

Science de base des industries des matières plastiques. Par Prof. H. Mark, avec la collaboration de Prof. T. Alfrey et Prof. R. B. Mesrobian. Pp. xv+548. (Paris: Masson et Cie., 1950.) 3150 francs.

THIS substantial book provides an up-to-date, detailed and excellently documented account of the physics and chemistry of large molecules. A useful feature is the full description given of the light-scattering method for the determination of molecular size and shape. The mechanical properties of polymers are treated thoroughly, as is the phenomenon of 'ageing'. On the chemical side, copolymerization and emulsion-polymerization are selected for discussion of the scientific principles involved. There is an interesting final chapter on the preparation and properties of *cyclo*-octatetraene, included because of its interest in connexion with the synthesis of new monomers. The book is based on a series of lectures given by Prof. H. Mark in Liège in 1948, and the Belgian editors are to be congratulated on their initiative and on their meticulous translation and excellent presentation of the material.

D. P. Riley

A Short Guide to Chemical Literature

By Dr. G. Malcolm Dyson. Pp. vii+144. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1951.) 8*s*. 6*d*. net.

IN arrangement and general treatment this book is an up-to-date version of Dr. F. A. Mason's "An Introduction to the Literature of Chemistry" published a quarter of a century ago, though the treatment is somewhat fuller, and a chapter, "Works of Reference on Medicinal Chemicals", replaces that on the "Special Literature on Dye Chemistry" in Mason's book. There is further a good chapter on "Making a Search in the Literature" which extends that in Mason's book, and an appendix giving an example of an organic chemical search. The book, moreover, contains two other useful appendixes: the first of these deals with some old and obsolete journals; the second gives a list of journal years and volume numbers more extensive than that to be found in "The Chemist's Yearbook" and covering the interruptions and changes of the past ten years or so. The book is admirably designed to serve its purpose. It is admittedly selective and cannot well be criticized on the grounds of omissions. One or two slight suggestions might, however, be ventured. The section dealing with historical text-books omits Bugge's "Das Buch der grossen Chemiker". If only for its copious references, this is a much more valuable work than several of those included. Among the list of chemical periodicals, the omission of the *Transactions of the Institution of the Rubber Industry* is surprising, and the *American Dyestuffs Reporter* might have been included among those dealing with dyes and textiles. Similarly, *Biological Abstracts* or *Abstracts of World Medicine* would appear to be at least as worth including among the abstract journals as *Excerpta Medica*.

Audubon Water Bird Guide

Water, Game and Large Land Birds, Eastern and Central North America from Southern Texas to Central Greenland. By Richard H. Pough. (Sponsored by National Audubon Society.) Pp. xxviii+352+48 plates. (Garden City, N.Y.: Doubleday and Company, Inc., 1951.) 3.50 dollars.

THIS excellent little book by R. H. Pough is a guide to the birds to be found on or near the marshy and watery areas of eastern and central North America. It is published under the sponsorship of the National Audubon Society, the many bird portraits in colour being by Don Eckelberry, while the black-and-white sketches are from the pencil of E. L. Poole, both of whom are worthy upholders of the tradition of the great bird artist Audubon.

The field covered is a wide one. It embraces not only truly aquatic species such as grebes and petrels but also birds of the marshes and birds associated with marshy areas. We read of herons, bitterns and egrets, plus ducks, geese and swans; we come to waders and even game birds and birds of prey.

A considerable amount of interesting information is given under the heading of 'habits', including the greatest age known to have been attained by the species under consideration; for example, the osprey twenty-one years, golden eagle thirty years and gannet sixteen and a half years. But the last-mentioned would not necessarily be an old bird; it might, indeed, be but in the prime of life, for there are grounds for believing the gannet lives long.

Frances Pitt

OBSERVATION OF A LINE IN THE GALACTIC RADIO SPECTRUM

Radiation from Galactic Hydrogen at 1,420 Mc./sec.

THE ground-state of the hydrogen atom is a hyperfine doublet the splitting of which, determined by the method of atomic beams, is 1,420·405 Mc./sec.[1]. Transitions occur between the upper ($F = 1$) and lower ($F = 0$) components by magnetic dipole radiation or absorption. The possibility of detecting this transition in the spectrum of galactic radiation, first suggested by H. C. van de Hulst[2], has remained one of the challenging problems of radio-astronomy. In interstellar regions not too near hot stars, hydrogen atoms are relatively abundant, there being, according to the usual estimate, about one atom per $cm.^3$. Most of these atoms should be in the ground-state. The detectability of the hyperfine transition hinges on the question whether the temperature which characterizes the distribution of population over the hyperfine doublet—which for want of a better name we shall call the hydrogen 'spin temperature'—is lower than, equal to, or greater than the temperature which characterizes the background radiation field in this part of the galactic radio spectrum. If the spin temperature is lower than the temperature of the radiation field, the hyperfine line ought to appear in absorption; if it is higher, one would expect a 'bright' line; while if the temperatures are the same no line could be detected. The total intensity within the line, per unit band-width, should depend only on the difference between these temperatures, providing the source is thick enough to be opaque.

We can now report success in observing this line. A micro-wave radiometer, built especially for the purpose, consists mainly of a double superheterodyne receiver with pass band of 17 kc., the band being shifted back and forth through 75 kc. thirty times per second. The conventional phase-sensitive detector and narrow (0 016 c./s.) filter then enable the radiometer to record the apparent radio temperature *difference* between two spectral bands 75 kc. apart. These bands are slowly swept in frequency through the region of interest. The overall noise figure of the receiver, measured by the glow-discharge method[3], is 11 db., and the mean output fluctuation at the recorder corresponds to a temperature change of 3·5°. The antenna is a pyramidal horn of about 12° half-power beam-width. It is rigidly mounted at declination −5°; scanning is effected by the earth's rotation.

The line was first detected on March 25, 1951. It appeared in emission with a width of about 80 kc., and was most intense in the direction 18 hr. right ascension. Many subsequent observations have established the following facts. At declination −5° the line is detectable, by our equipment, over a period of about six hours, during which the apparent temperature at the centre of the line rises to a maximum of 25° above background and then subsides into the background. The source appears to be an extended one approximately centred about the galactic plane. The frequency of the centre of the line, which was measured with an accuracy of ±5 kc., was displaced some 150 kc. above the laboratory value, and this shift varied during an observing period. Both the shift and its variation are reasonably well accounted for by the earth's orbital motion and the motion of the solar system toward Hercules. The period of reception shifts two hours per month, in solar time, as it ought to.

Some conclusions can already be drawn from these results. Extrapolation of radio temperature data for somewhat lower frequencies[4] suggests that the background radiation temperature near the 21-cm. line is not more than 10° K. Then the hydrogen spin temperature is not more than 35° K., if the source is 'thick'. But we can calculate the opacity of the source on the assumption of a spin temperature of 35° K. and 1 $atom/cm.^3$, using only the observed line-width and the matrix element of the transition in question, and we obtained 900 light-years for the absorption-length. As this is much smaller than galactic dimensions, we conclude that the temperature observed corresponds indeed to the spin temperature at the source. To the extent that 'self-absorption' contributes to the observed line-width, the true absorption length at the frequency of the centre may be *less* than that computed. Further evidence for relatively high opacity is the absence of large frequency-shifts, which would be expected to arise from galactic rotation were the opacity-thickness comparable to the size of the galaxy. This conclusion is contrary to the prediction of Shklovsky[5], who has recently discussed the possibility of detecting galactic line radiation.

We have made rough theoretical estimates of the efficacy of various processes through which energy is exchanged between the hydrogen hyperfine levels and the other thermal reservoirs in the interstellar matter plus radiation complex. Of these we find exchange with the radiation field (involving spontaneous emission) and exchange with gas-kinetic energy of the hydrogen atoms (via H–H collisions) much the most important, with the latter process probably dominant. This is consistent with the observation, and if correct implies that the gas-kinetic temperature of the hydrogen exceeds, but not greatly, the spin temperature. The estimated spin relaxation time for these processes is of the order of 10^3 years.

This work was assisted by a grant from the Rumford Fund of the American Academy of Arts and Sciences.

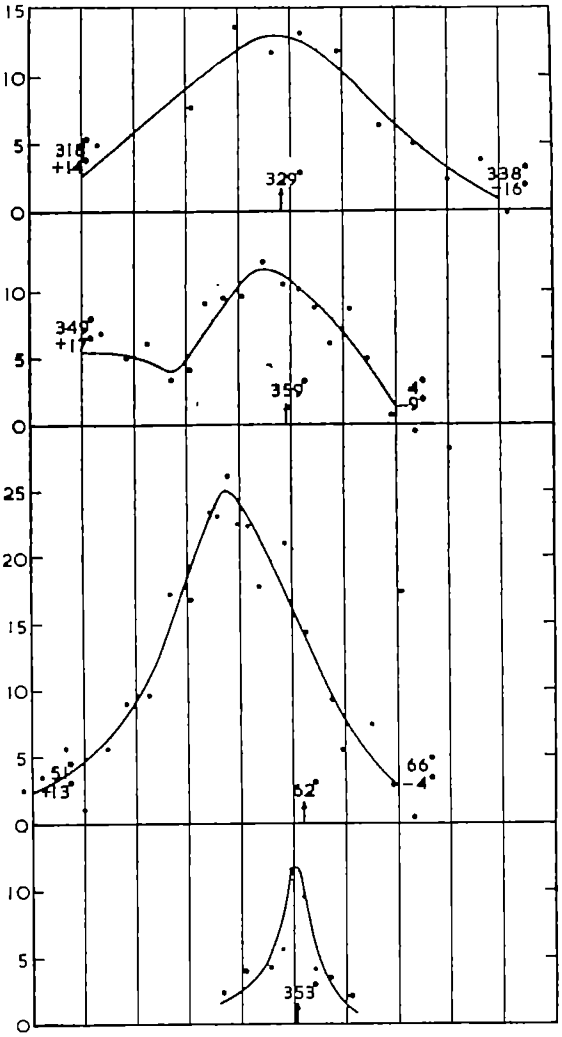
The Interstellar Hydrogen Line at 1,420 Mc./sec., and an Estimate of Galactic Rotation

FOLLOWING a suggestion made by Dr. H. C. van de Hulst in 1944[1], attempts have been made to measure the radiation at 1,420 Mc./sec. (λ21 cm.) emitted by atomic interstellar hydrogen. The first experimental evidence for the presence of this interstellar emission line was obtained by Ewen and Purcell on March 25, 1951 (see the preceding communication). In the Netherlands, the first successful measurements were made on May 11.

The receiver consists of a double superheterodyne instrument, with a crystal-controlled first local oscillator, which is switched between two frequencies 110 kc. apart thirty times per second by a reactance modulator. By varying the frequency of the second local oscillator, the two frequencies can be moved together through a 4-Mc. wide pass band at 1,420 Mc. The pass band of the second i.f. channel is 25 kc. wide. Behind the usual phase-sensitive detector a narrow-band filter with a time constant of 12 sec. is used. So the difference between two frequency bands 110 kc. apart is measured. The noise factor of the receiver has not yet been measured. The losses in the coaxial antenna cable are rather high, and an effective noise factor of the whole receiving system of 25 has been deduced from other measurements with the sun as a source of noise. Important parts of the receiver have been constructed at the Philips Laboratory in Eindhoven under the supervision of Dr. F. L. Stumpers.

The receiver has been mounted behind a movable paraboloid of 7·5 m. aperture and 1·7 m. focal-length at the radio station at Kootwijk, which was kindly put at our disposal for these measurements by the Radio Department of the Post and Telegraph Service. The beam-width at half-power is 2·8°.

The results of the measurements made on a few of the first tracings are shown in the accompanying graphs. While these tracings were being made, the instrument was left in a fixed position relative to the earth, the motion across the sky being provided by the earth's rotation. The frequency of the second local oscillator is switched every 3 min. between positions in which either of the two pass bands coincides with the spectral line. The first position gives a positive, the other a negative, deflexion on the recording meter. The curves show the intensity as function of the right-ascension; the interval between successive vertical lines is 20 min. of time. The point at which each sweep crossed the galactic equator has been marked with an arrow, accompanied by a number giving the corresponding longitude. The galactic co-ordinates at the beginning and end of each tracing have also been indicated. The curves shown may be slightly distorted because the radial components of the orbital motion of the earth, of the sun's motion relative to the nearby interstellar clouds and of differential galactic rotation are different for the various directions. However, we do not believe that these effects will have seriously affected the general shapes of the records, except for latitudes less than $1\frac{1}{2}$°, where in some directions the line is greatly widened by galactic rotation, and the measured intensities will be too small.



It is evident from the wide spread in galactic latitude that the clouds observed must be relatively close to the earth. From the width of the emission line observed in the region of the centre of the Galaxy, where the rotation of the galactic system does not affect the line, it is found that the random velocities average about 5 km./sec. in one co-ordinate, which agrees approximately with what had been found from absorption lines in the visual region. With such small velocities it is unlikely that the gas extends to more than an average distance of about 50 parsecs from the galactic plane. With an average latitude of the order of 8°, the gas seen in the general direction of the centre cannot then be farther away than 300 or 400 parsecs. In Cygnus the distance may be twice this amount.

These small distances might be taken as an indication either that the more central parts of the Galaxy are devoid of atomic hydrogen, or else that within a distance of between 500 and 1,000 parsecs in the galactic plane the gas becomes optically thick in the wave-length of this line. Although we should like to reserve a definite judgment until more complete measures have been obtained, we believe the latter alternative is the more probable on the basis of the results so far available.

In order to test the presence of radiating hydrogen in the inner regions of the Galaxy, measures have been made across the Milky Way at l = 355°, 30° from the centre, where the change of frequency due to differential galactic rotation should make it possible to observe the gas up to large distances. Provisional measures indicate that the emission line in this direction has an effective width of about 330 kc./sec., or 70 km./sec., and that the rotational velocity of the galactic system at a distance from the centre equal to half the sun's distance from the centre is approximately 190 km./sec. This agrees well enough with the rotational velocity of 205 km./sec. computed from a schematic model of the galactic system[2]. (In both cases a value of 270 km./sec. has been assumed for the rotation near the sun.)

The graph at the bottom shows the results of a registration across the Milky Way at 355° longitude and at a frequency 250 kc./sec. lower than the normal frequency of the line, corresponding to a differential radial velocity of +55 km./sec. The gas clouds observed at this frequency are presumably situated at an average distance of about 8 kiloparsecs. It may be noted that the spread in latitude is quite small, and may roughly correspond to the beam-width of the instrument, as would be expected for these large distances.

The tracings reveal many irregularities in distribution. The extension to high positive latitudes in the second graph may possibly be connected with the well-known dense clouds in Ophiuchus. The maxima in the Cygnus region lie systematically about 2½° south of the galactic circle at longitudes between 40° and 45°, while between 56° and 62° they occur roughly 3° north of the plane. Though no weight should be attached to the exact differences in height of the various sweeps, the intensities in Cygnus appear to be definitely higher than in other regions (except in that opposite the centre). This may be ascribed to the effects of galactic rotation. The fact that the intensity is also lower in the direction towards the centre, where these effects are presumably negligible, is possibly due to the superposition of continuous background radiation, which has probably a considerable intensity in this direction.

The measurements reported in this communication are of a provisional nature. Improvements in the receiver are possible, and are now being made in preparation for more systematic measurements.

The investigation has been made possible by grants from the Netherlands Organization for Pure Research (Z.W.O.).

VARIATIONS IN THE CHEMICAL COMPOSITION OF STRATOSPHERE AIR

By Dr. K. F. CHACKETT, Prof. F. A. PANETH, F.R.S., P. REASBECK and B. S. WIBORG

Londonderry Laboratory for Radiochemistry, University of Durham

In a previous article[1] analyses of upper air samples obtained from 52–66·5 km. height by means of *V2* and Aerobee rockets were described, and it was shown that in all cases the composition of the samples was nearly the same as at ground-level, with respect to the ratio of helium, neon and argon to nitrogen. At the same time it was pointed out that some uncertainty must be attached to the helium values because the air was sent to us in glass vessels. Recently, we received, from the University of Michigan, stratosphere air in the original steel bottles in which the samples had been collected; a new and improved sampling technique had been employed, and in the meantime our method of analysis had also been further developed. We now wish to communicate our latest results, which provide evidence for gravitational separation between 64·3 and 71·8 km. height (M.S.L.). Details of the experimental procedure will be published later.

We owe the following information about the new sampling arrangements to the scientific workers of the Department of Aeronautical Engineering, University of Michigan[2]. Three evacuated steel bottles were located immediately behind the hollow nose cone of an 'Aerobee' rocket. The bottles were soldered to thin copper tubes, one inch in diameter, the sealed-off ends of which projected into the cone. The latter was ejected automatically just before sampling. At a predetermined instant a steel knife was arranged to cut through one tube, and five seconds later this was squeezed shut at a lower point by a pyrotechnically operated vice. The second and third bottles were opened and shut at successively later times. Control experiments had shown that the sealing mechanism gave satisfactory vacuum-tight seals without the use of solder.

A successful flight took place from the White Sands Proving Ground in New Mexico on December 19, 1950. After recovery, the three steel bottles were dispatched to us and their contents analysed by our micro-method for oxygen, nitrogen and the inert gases helium, neon and argon. Since our previous work, an entirely new apparatus had been built with several improvements over the old model. Thus, the air pipette was of smaller volume, enabling us to take smaller amounts of gas (between 0·07 and 0·10 c.c. s.t.p. for each analysis); the same pipette was used for the helium–neon analysis and for the nitrogen–argon analysis; and the fractionating column consisted now of fifteen units instead of twelve, each smaller than formerly, and operated by means of a mechanical device which could be set to perform any number of fractionations and then stop.

In general, runs on the stratosphere air were sandwiched between runs on ground-level air, so that a good check could be kept on the satisfactory working of the apparatus. As we found in the earlier work, the oxygen content of the samples was much below normal in spite of the fact that the sampling vessels were always cold. It is impossible to assume that there really is this deficit of oxygen in the

Sample		Height (km.)	Date of sampling	Date of first analysis	Oxygen	Helium	Neon	Argon
16*A*	Glass vials	49·6–53·6	2.6.49	4.8.49	0·61	0·96	0·98	1·00
25*D*		50·4–53·3	6.12.49	17.4.51	0·60	0·98	1·00	1·00
15*B*		53·6–57·7	2.6.49	25.7.49	0·12	1·00	1·00	1·01

B-9		69·6–71·8	19.12.50	9.5.51	0·03	1·49	1·07	0·95

upper air, and we suppose that the walls of the bottles and connecting tubes were so well cleaned during the initial pumping and degassing that they were able to take up most of the oxygen at room temperature during the interval—five to six months—between the flight and the analysis.

In view of the ever-present danger of a partial loss of oxygen during sampling, it has always been our habit to express the figures for the rare gases in relation to oxygen-free air or, in other words, to the nitrogen + argon content; since we have now found some variations in the argon content, we think it best to relate all figures to nitrogen. The accompanying table gives for each gas the value of the ratio:

$$\frac{\text{volume of gas, relative to nitrogen, in sample}}{\text{volume of gas, relative to nitrogen, in ground-level air}}.$$

For convenience we have included in the table the results of previous analyses also. All figures are quoted to two places of decimals only, although the errors calculated from individual experimental results (usually two or more) are often less than one-half per cent. The figure marked with an asterisk is unreliable owing to contamination by, apparently, hydrogen.

The first six samples in the table show no appreciable variation in chemical composition from ground-level air. The results of 16*A*, 15*B*, 1*B* and 3*B* have been published before[1]; 25*D* and 19*D* were later analysed for the special reason that McQueen[3] had found in air from these samples as well as from 15*B* a shift in the relative proportion of the nitrogen isotopes which he interpreted as an indication of gravitational separation. Our figures are in contradiction to this interpretation, as has already been pointed out with respect to 15*B* by the workers at the University of Michigan[4], whose own experiments confirm our findings. However, while we are certain about the correctness of the analyses, it is perhaps not impossible that contamination by ground-level air during the process of sampling has obscured shifts in the chemical composition.

Quite different are the results of the last flight. In every one of the three steel bottles we found a marked increase of the helium and neon content and a deficit of argon. The shift of the helium percentage is greater than that of the other two gases. All this is in qualitative agreement with the supposition that the samples come from a region in the stratosphere where gravitational separation has been effective.

It is the first time that such an effect has been observed with certainty. In earlier experiments we found a small increase of helium at heights between 21 and 25 km., and M. Shepherd and E. Regener a deficit of oxygen between 19 and 29 km.[5]; but we were reluctant to consider the evidence as conclusive[6]. It is not safe to rely on helium analyses if the sample has been stored in a glass vessel, and contact with stop-cock grease is sufficient to reduce appreciably the oxygen content[1]. In Regener's experiments there was a further source of possible error: his stratosphere sample was during the whole time in contact with metallic copper, so that, according to our experience, disappearance of some oxygen was to be expected.

Of the three steel bottles used in the last flight, the first one, *B*-6, opened and sealed perfectly. As to *B*-8, we were informed that the opening may have been poor as the knife was at the time of recovery in an unexpected position. In *B*-6 we found 0·388 c.c. of air (s.t.p.), in *B*-8 only 0·185, but as the sample came from a greater height there seems to be no reason to suspect the essential correctness of the sampling; it is qualitatively in agreement with expectations to find in *B*-8 a stronger shift in composition than in *B*-6. Concerning *B*-9, however, we doubt whether the sample is representative for the height given. Here, as well as in *B*-8, the opening might have been incomplete as the knife had cut only half-way; nevertheless, we found in this bottle 0·535 c.c. (s.t.p.), a considerably greater volume of air than in either *B*-6 or *B*-8, in spite of the greater height. As at the same time the shift in composition is not even as strong as in *B*-6 (see especially the very accurate argon figures) we strongly suspect that, after the sampling at about 70 km., the sealing was not perfect and that afterwards some ground-level air had leaked in; after recovery the sealed copper tubing was covered with glyptal, but that does not exclude the possibility of a previous leakage. If from the volume of gas measured in the other bottles we calculate the amount to be expected in *B*-9, we find that only about a fifth of the quantity contained came from 70 km.; assuming the rest to be ground-level air, we can allow for this contamination. Instead of helium 1·49, neon 1·07 and argon 0·946 we obtain the following 'corrected' figures for *B*-9: helium 3·44, neon 1·35 and argon 0·73. We feel that this procedure is the best in the circumstances, but even if the latter figures are nearer the true value than those obtained by direct analysis, they are very rough.

Our figures do not agree quantitatively with any simple theory. This, however, is scarcely surprising, since the samples may be the result of many alternating phases of gravitational separation and of remixing. Another possibility is that an initially homogeneous layer began to separate gravitationally, but owing to the different mean velocities of the constituent molecules the helium reached its equilibrium concentration with respect to nitrogen more completely than the heavier gases. Taking the helium ratios for *B*-6 and *B*-8 as representing the composition at the midpoints of the sampling intervals, it may be shown that a good fit is obtained with a temperature of 230° K., and with the midpoint of *B*-6 as 3·0 km. above the level at which separation commences. The calculated figures for the neon in *B*-6 and *B*-8 are then 1·13 and 1·26, the argon figures 0·83 and 0·71 respectively; the calculated helium, neon and argon ratios in *B*-9 are then about 2·8, 1·4 and 0·6 respectively. These calculations are, however, of little value except as an illustration of the deviations from a simple theory, if only because it is estimated that the actual temperature at these heights is nearer 280° K.[7].

Since it is proved now that the sampling technique of the Michigan team of scientific workers can reach heights in which diffusive separation becomes effective, it is hoped that more samples from these, and from even greater, heights will soon be collected. Only if more experimental material is available will it be possible, and worth while, to try to develop precise ideas about the stillness, or otherwise, of the stratosphere at heights from 64 km. upwards. So long as about 0·1 c.c. of air (s.t.p.) can be collected (containing normally 5×10^{-7} c.c. helium, $1 \cdot 8 \times 10^{-6}$ c.c. neon and $9 \cdot 3 \times 10^{-4}$ c.c. argon), we shall be able to carry out on each sample at least one analysis of these three gases with the present accuracy of 1 per cent. Air from greater heights may show such marked variations in composition that still smaller samples and, accordingly, a somewhat reduced accuracy, will give valuable information.

We wish to express our thanks to Messrs. L. M. Jones and E. A. Wenzel, of the Engineering Research Institute of the University of Michigan, for their long-distance collaboration, and to the United States Signal Corps Engineering Laboratories who have sponsored and supported the research at Michigan. We also acknowledge with gratitude financial assistance rendered by the Gassiot Committee of the Royal Society, and one of us (P. R.) a Further Education and Training grant.

MODERN INSECTICIDES AND THE BALANCE OF NATURE*

By Dr. D. STEWART MacLAGAN

Head of Zoology Dept., and Adviser in Zoology, West of Scotland College of Agriculture

SINCE man first scratched the soil in an endeavour to obtain more food, he has had to contend with the vicissitudes of a hostile environment. Of the factors inimical to increased productivity, few are of greater significance than the direct and indirect toll exacted by insects and their allies; the loss in world crop-production alone being at least ten per cent, and double that figure according to other estimates. This is not so remarkable if it is borne in mind that nearly three-fourths of all species of animals are insects.

For hundreds of years, therefore, man has been driven of necessity to combat his insect enemies. Within the past decade, however, chemists have synthesized new pesticides which have penetrated the realms of plant protection, veterinary and medical hygiene, at great speed. Despite the remarkable insecticidal and acaricidal properties of these new substances they are not the universal panaceas which was portended in the first flush of enthusiasm. They have their limitations and dangers, and ignorance of their ultimate effects has led to their abuse. For good or ill, however, there is no doubt that these artificial aids to pest control have received a warm welcome from diverse sources.

The two main groups of these 'wonder' insecticides are the chlorinated hydrocarbons and the organophosphates. Members of both groups are now in use throughout the world in connexion with pest problems which seemed well-nigh insoluble. With the advent of DDT, BHC, DNT, HETP, etc., man's potential control over the lower orders was never so powerful as it is to-day, and the 'discovery' of these chemicals will rank as a major contribution of science to the world.

Some of the original claims made for DDT were exaggerated; but used with discretion, it is probably the most generally useful insecticide available being highly toxic to most insects. A unique feature—not without danger—is its extraordinary persistency, which renders DDT of special value where good persistence on foliage is essential. Thus, DDT has proved its effectiveness against a variety of plant-feeding caterpillars, weevils, pollen and flea beetles, several moths, and against the cotton jassid in the Sudan. Mosquitoes and other flies, fleas and lice, are highly vulnerable. Throughout the stock-rearing countries of the world, this 'penicillin of insecticides' is proving a boon to harassed stockmen in their struggle against blowflies, keds and ticks. Fortunately, DDT is less harmful to bees than was first suspected; but no undue risks should be taken in this respect, such as spraying open blossom.

Another 'wonder' insecticide is the gamma-isomer of benzene hexachloride. Although of lower persistency, it has a degree of volatility not possessed by DDT. This accounts for its spectacular results as a soil-insecticide, especially against wireworms—formerly responsible for losses of 0·5 cwt. per acre of English wheat and oats, for every 100,000 wire worms per acre. In addition, BHC gives good control of certain aphides, sawflies, root-maggots and leaf-miners. Abroad, the age-old menaces of locusts and termites may eventually be eliminated by this new weapon. So toxic to locusts is gamma-BHC that 3 gm. are enough to kill a ton of them. Equally remarkable results are being obtained in the control of mange-mites and ticks; for example, the scab-mite which has ravaged the sheep-flocks of the Old World for two thousand years can now be eradicated by one dipping in a BHC suspension.

The synthetic organophosphates originated in Germany, during the Second World War, as substitutes for nicotine. Of these, HETP was the first to be used commercially; but has been partially superseded by DNT or parathion, of which the outstanding feature is its extreme toxicity to aphides and spider-mites—both largely unaffected by the chlorinated hydrocarbons. Parathion is non-ovicidal and seldom persists actively on foliage for longer than three days. Of special interest is the discovery by American and Australian investigators that parathion gives commercial control of chrysanthemum eelworm, thereby suggesting a solution of the eelworm problem in other crops.

These are the principal achievements of three insecticides in world-wide use; but so many are appearing on the market that some may be outmoded sooner than seemed probable a few years ago. As these chemicals have not been received with universal approbation, what are the charges that have been levelled against them? The presumed hazards to human health, through the cumulative effects of toxic residues, falls outside the scope of this paper, so that the other potential danger can now be considered.

---

* Substance of a paper read on August 10 before Section D (Zoology) of the British Association meeting at Edinburgh.

Two years ago, in a contribution to *Discovery*, I remarked that "because of the greater susceptibility of numerous parasites and predators than the pests themselves, and the rapid resurgence of pests in the virtual absence of natural enemies, the indiscriminate use of these new chemicals might seriously upset the balance of nature". To what extent has this prognostication materialized?

Evidence from numerous sources leaves no doubt that sprays of DDT on fruit-trees lead to an increase of 'red spider' (*Paratetranychus* spp.). This was presumed to be due to destruction of natural enemies; but more recent work in the United States and in Holland supports the view that DDT has also a direct stimulating effect upon the reproduction of the mites. Nevertheless, DDT can kill thirty or more of the insect enemies of red spider, and if used soon after bud-burst it may destroy many beetles which act as pollinators. Mealybugs and many species of 'greenfly' are practically unaffected by DDT, and tend to increase when it is used alone. This is due to its lethal action upon the larvæ and adults of predators such as hover flies, lacewings and ladybird beetles. Similarly, the use of DDT against certain root maggots intensifies the injury, apparently by killing predators of the puparia.

Recent studies of the fauna of apple-orchards in Nova Scotia have revealed a tangled skein of interrelationships between phytophagous mites and insects, parasites, predatory mites, bugs and beetles: additional complications having followed the use of insecticides and fungicides. In general, it seems that the populations of red spider and scale insects in so-called 'neglected' orchards are lower than in orchards subjected to spraying with DDT. In several areas, DDT has so reduced the activities of the *Aphelinus* parasite of woolly apple-aphid that the latter has required treatment with BHC. Aerial application of DDT (1 lb./acre) has given reasonable control of forest defoliators in the United States, without causing permanent damage to invertebrates serving as fish-food in the streams and lakes; but in another investigation the density of invertebrates was greater one year after spraying than before, suggesting some interference with the natural balance. It is considered inadvisable to use more than double the above rate to avoid harm to birds, and treatment should not be carried out during the nesting season.

Charges against BHC include the causation of greater injury by cotton bollworms (*Heliothis* spp.) due to destruction of predatory bugs, and an increase of sugar cane borer (*Diatraea*) through destruction of the egg-parasites (*Trichogramma* spp.). Nor is there any doubt that dusts of BHC are extremely toxic to bees and other pollinators, so that on no account should they be used on open blossom. Beans dusted with this chemical to control black dolphin (*A. fabae*) have failed to set seed—a result of interference with cross-pollination. Earthworms are not seriously affected, whereas older insecticides such as derris and lead arsenate are highly toxic to them. Neither DDT nor BHC gives the spectacular knockdown of pyrethrum; but like derris, both are deadly to fish. Although parathion is potentially less dangerous to beneficial insects because of its much lower persistence than either DDT or BHC, it is quite toxic to many predators of aphides and spider-mites.

The adverse effects of insecticides on beneficial species is by no means a new problem; but the potency and persistency of modern synthetics have raised specific problems concerning their appropriate application to avoid abuse. It has been realized for many years that tar-oil winter washes were directly associated with the increase of red spider in the orchards of southern England, and that they were not favourable to the establishment of the imported parasite (*A. mali*) of woolly apple-aphid. American investigators concluded in 1931, and again in 1935, that sprays of lead arsenate were seriously reducing the efficiency of an important parasite of the codling moth, and that egg-parasitism was lowest in orchards tended according to the most up-to-date rules of husbandry. Applications of lime-sulphur have repeatedly been noted as ultimately leading to outbreaks of scale insects, due to paralysis of their parasites; and in 1941, cryolite was found to cause such a high mortality among predatory coccinellids that they were incapable of exercising their former control of citrus mealybugs. Both old and modern sprays, designed to combat codling moth, generally result in heavier infestations of red spider and leaf hoppers. These adverse effects can nevertheless be minimized by appropriate choice of the chemical and judicious timing of its application. For example, nicotine dust does little harm to larval coccinellids and syrphids, and arsenicals are relatively innocuous to many parasites and predators. When there is a differential emergence, in time, of hosts and parasites, it is often possible to restrict spraying to periods when the parasites are least vulnerable. Maximum injury to beneficial insects is most likely to result from spraying when they are in maximum abundance, namely, during the later phases of outbreaks.

All these ameliorative measures designed to conserve parasites and predators, and the outcry about adverse effects of insecticides, are based on the assertion that natural enemies have a significant role in suppressing potential pest-populations below the 'level of economic significance'. The words in inverted commas should be noted, because the role of natural enemies (including pathogenic organisms) in eventually effecting the collapse of insect-outbreaks is an entirely different subject. Since the multiplication of parasites and predators is dependent on the density of the host-insect, economic control is feasible only if the host is always present to a density which favours the natural enemies, without causing damage to the food-plant of the host—a finely adjusted interaction indeed. It must be emphasized, also, that mortality attributed to biotic factors is only a part of total mortality, which is the combined result of many factors.

Of the numerous projects which have been launched with the objective of controlling pests by the introduction of parasites and predators, only some twenty have been really successful—and mainly in tropical or semi-tropical regions of the world. Projects for augmentation of native parasites have proved disappointing and costly in relation to the increment of parasitism. Even in countries of an old-established agriculture, where pests and their enemies have had ecological opportunities of attaining relative stability, there is no dearth of pest-outbreaks. A survey of old books and periodicals shows that, even in Britain, crop and stock have suffered intermittently for centuries, and before the use of insecticides was given any consideration. This carries no implication that it is not worth while making the fullest use of all available natural enemies of pests, but simply that they cannot be solely relied upon as permanent controlling agents. Indeed, no less an authority on biological control than Dr. W. R. Thompson makes the following statement: "The discontinuity and variability in habitats, produced by physical factors, both in time and space, is the primary extrinsic factor of natural control".

In view of the repercussions, already outlined, which have followed the application of some of the new chemicals, it is of interest to consider briefly the kind of happenings which may be expected, on theoretical grounds, to follow the operation of any drastic mortality factor in a biological complex of phytophagous insects, predators and parasites. Volterra gave quantitative expression to predator–prey interactions, and has enunciated basic generalizations or 'laws', of which the third is his 'Law of the Disturbance of the Averages'; stating that if two species living together (one feeding on the other) are destroyed in proportion to their numbers, the average number of the prey increases and that of the predator diminishes.

The interesting practical significance of this law is that while an insecticide (or any other highly destructive factor) causes an immediate reduction of the damage, the effect is temporary even in respect of species which are materially suppressed by natural enemies. These are dependent for their increase on the population-density of the host, so that their increase is much slower than that of the host when both population-densities are low. Hence, impoverishment of a natural complex of this kind temporarily releases the host from control, and there follows a series of violent fluctuations in the average density of the host, until the natural enemies re-establish the former relative stability. During this period, before the natural enemies can exercise adequate control, the pest may attain densities of serious economic import.

That such effects occur, sometimes, after application of a potent insecticide, is well exemplified by the resurgence of aphides and red spider, following the application of DDT to fruit-trees; but here the trouble is intensified by the prolonged toxicity of the residues to the notoriously susceptible parasites and predators. This exemplifies an important point concerning the application of insecticides (particularly in respect of those with persistent residues), namely, the risk of encouraging some *other* pest through destruction of its natural enemies, and more so if the second species is not seriously affected itself by the chemical.

When a species that is known to be significantly affected by biotic factors of mortality attains 'pest' status, then the plant doctor is indeed placed in a dilemma. He must either advise the avoidance of insecticides, to give the natural enemies free rein, and warn the grower of some recurrent injury; or else he must advise the judicious use of insecticides, to obtain immediate amelioration of the trouble, and warn the grower about repeating the treatment to avoid more serious injury. The correct course of action can be determined only after gauging the economics of the situation, but with profit-margins becoming increasingly dependent on yield and high-quality produce, the fundamental issue for many growers is: 'Can I afford *not* to spray?'.

As to the likelihood of disturbing the so-called 'balance of Nature', the majority of biologists realize what Darwin implied even if his choice of the word 'balance' may appear unhappy to a modern physicist. The quasi-equilibrium eventually attained in Nature is not necessarily, however, to the benefit of man. Interference with Nature is generally accepted as unavoidable, if productivity is to be increased. Modern techniques for increasing yields are certainly conducive to increasing 'imbalance', through gross interference with organic Nature; and unfortunately, in tilting the balance favourably in one direction there frequently ensues a series of unforeseen repercussions. The ultimate re-assertion of Nature is unusually well demonstrated in the world of insects.

Surveying the evidence in retrospect, there is no doubt that extensive and indiscriminate use of the new potent and persistent pesticides could bring about serious consequences; not only by disturbing predator–prey and host–parasite interactions, as outlined heretofore, but also by leading to the production of chemical-resistant strains of pests. Even now, on many farms in Illinois, the resistance of house-flies to DDT has become so high that a change-over to other insecticides is considered desirable. In general, the potential dangers of some of the new synthetics would appear to be least when applied to crops under rotation in temperate climates, and greatest when applied to non-rotated crops under tropical conditions.

The latest developments, in the form of systemic insecticides, may provide the plant doctor with a way out of his dilemma. As a result of war-time investigations in Germany, a group of insecticidal compounds were 'discovered' and found to be absorbed by the leaves and roots of plants. Their 'internal' or systemic action is negligible in plants which have stopped growing, however; and a few plants are intolerant. None the less, these systemic insecticides, for example, octamethylpyrophosphoramide, have a remarkable combination of desirable features; being deadly to sap-suckers, relatively non-toxic to beneficial insects, of reasonable persistency in the plant, and harmless to mammals if used in appropriate dilutions. The supreme advantage of an insecticide such as the above is that the natural enemies of the pest are enabled to reinforce the artificial control of the chemical. Incidentally, this decreases the risk of development of resistant strains of the pest. An 'internal' insecticide has also obvious advantages against leaf-miners, stem-borers, root-suckers, and other species which are difficult to control because of their inaccessibility. Further exploration of the uses and limitations of systemic insecticides (and fungicides) is eagerly awaited.

A survey of the situation concerning the new insecticides seemed desirable if for no other reason than to direct attention to the various factors which are involved in natural controlling complexes. Their analysis, involving assessment of the relative significance of mortality factors, has become of considerable urgency so far as insects are concerned, as a direct result of the synthesis of these remarkable new pesticides and their appearance on the market in ever-increasing profusion. The suitability of an insecticide is not merely a question of toxicity and cost—the chemist can tell us about that—it is the ecologist who must be the final adjudicator as to the appropriate uses of these powerful artificial aids to pest control. It would be most unfortunate should they be denigrated through incompetent or over-enthusiastic handling.

LIFE AND WORK IN EXTREME ENVIRONMENTAL CONDITIONS

It must have been almost without precedent that Section A (Mathematics and Physics) of the British Association should have devoted a session at the recent Edinburgh meeting to so biological a subject as "Life and Work in Extreme Environmental Conditions". The title might have included pressure as well as temperature extremes; but the former were not considered by any of the speakers, and the morning was devoted entirely to the effects of thermal stress. The study of this subject is not new, for it began two hundred years ago; but it has been taken up again recently with some intensity, and its importance for industry and the Armed Services can scarcely be over-emphasized. Those who have been frustrated in their attempts to lay in a stock of fuel for the winter of 1951–52 may feel that it has considerable importance for the ordinary citizen.

The president of the Section, Sir David Brunt, was in the chair and the first paper was given by Dr. O. G. Edholm, who pointed out that the subject under discussion must be counted an unusual one since it had brought together physicists, psychologists and physiologists. Had Dr. Edholm realized what the discussion would bring forth, he might have said even more about the widespread interest of the subject. His paper dealt with the basic principles of heat regulation in man. He emphasized the relative constancy of the body temperature and discussed the various ways by which this is maintained. He directed attention to the fact that the various organs produce heat at different rates, and emphasized the over-riding effects of exercise and of the ductless glands in varying the amount of heat produced by the body as a whole.

The second paper, by Dr. F. Marsh, was the only one which did not deal with human physiology. The work he described had been done on rabbits at Abadan in the Persian Gulf, where he had studied the effect of raising their temperature by exposing them to the sun. The rabbit loses heat mainly by varying its respiration-rate and the amount of blood flowing through its tongue. Observations were made of the animals' respiration-rate, carbon dioxide output, rectal temperature, heart-rate and venous hæmoglobin. Dr. Marsh did not give any details of the methods he had employed to make these measurements, but his observations showed that after the body temperature had risen to a certain height, which varied from one rabbit to another, there was great danger of collapse and death at any time from then onwards for at least twenty-four hours, even if the animal was cooled to a normal temperature by placing ice on its fur, and if it appeared relatively normal after this had been done. In considering the application of this work to man, the chief conclusion was that prevention is better than cure.

Dr. N. H. Mackworth described work which he had done in an improvised wind tunnel at Fort Churchill in Canada on the effect of cold and wind in destroying touch discrimination in the fingers. This is an important matter where fine work is concerned because gloves destroy a man's manual dexterity. But so do cold and wind, so that to remove the gloves to do the job often leads to unfortunate results. Dr. Mackworth made two points which were no doubt noted by the physicists in his audience. In defining conditions for fine work out of doors, it is not enough merely to give the temperature and wind velocity. The reaction of the man and some way of measuring it are just as important, because, first, no two men are able to withstand extreme conditions equally well, and, secondly, acclimatization and practice can lead to great improvement in the performance of a single man. He illustrated this by showing how much better men accustomed to working out of doors performed in these experiments than those who normally did all their work in warm rooms.

A joint communication by Profs. E. M. Glaser and R. A. McCance dealt with some of the fundamental adjustments by which the temperature of the internal organs is maintained, and they pointed out that in order to achieve this the temperature of the peripheral parts of the body may vary very widely. The temperatures of the skin and limbs are usually lower, but may be higher than the mouth or rectal temperature. They also directed attention to the fact that some variation in the internal temperature is compatible with life and even with comfort, and that after the internal temperature has been raised or lowered by a degree or more it tends to stabilize itself for many hours at or near the new temperature even when the man returns to the original environment. In other words, the body is so organized that it tends to produce a balance between heat gain and heat loss rather than to maintain a fixed internal temperature. In this respect its regulating mechanisms may be compared with the governor of a steam engine rather than the laboratory thermostat which usually operates by cutting in and cutting out as the temperature of the bath varies.

Dr. T. Bedford drew upon his great experience of industrial work to bring out the facts that industrial efficiency depends very much upon the temperature at which the work is done. He showed, for example, that the output from mines is affected in this way and that there are interesting differences between the European miner and coloured workers. A wet-bulb temperature of 84° F. reduces the efficiency and output of European miners very materially, much more so than it does those of coloured people; this is probably because the European sets himself a relatively much higher standard in a cooler environment. Dr. Bedford produced many other instances of the effects of temperature. In hot industries, for example, the output tends to rise in winter, whereas in cold industries it tends to rise in the summer.

Warp breakages can be reduced by raising the temperature under which cotton is woven; but in hot humid environments human efficiency falls, so that a mean has to be found at which the man and the cotton thread can both survive. This has been shown to be about 75° F. (dry bulb) and 73° F. (wet bulb). Dr. Bedford concluded by quoting some work of Dr. Mackworth's which has shown that the reception errors of telegraphists rise very rapidly when the external temperature and humidity reach a certain point.

Dr. Ezer Griffiths was the last speaker on the programme. He discussed various ways of measuring temperatures and humidity as they applied to man and pointed out the failings of the kata-thermometer. He then described a mechanical man which has recently been designed and which can measure the heat absorbed by or radiated from itself by using electronic recording. The control panel, which Dr. Griffiths displayed, looked very complicated, although he said it was simple—as no doubt it was, compared with the physiological control panel in the hypothalamus.

Sir David Brunt opened the discussion by saying that he had encouraged the organization of this meeting as he was anxious to know how the environment which he had studied as a meteorologist affects the bodies which the physiologists set out to study. His idea had been to stimulate interest in the climatic conditions under which man ceases to work efficiently and to discover whether physiologists and psychologists are prepared to find out more about this. The lively discussion which followed centred largely upon the word 'comfort'. Miss M. V. Griffiths and others spoke about the advantages of floor heating. It was stated that if the temperature of the floor is 72–75° F. people in the room can be maintained in comfort when the temperature of the room itself is only 54° F., though this was doubted by Dr. Bedford—evidently one of the world's 'cold mortals'. The heating and ventilation of motor buses also came in for some discussion, a matter of some importance to many people to-day. The most satisfactory system seems to apply the heat near the floor and ventilate the bus near the ceiling. Reducing the humidity brought in on wet clothes and inseparable from expired air appears to be a very important matter in bus management because, apart from the comfort of the travellers, it greatly reduces the time which has to be spent by the maintenance staff in sponging down the interiors to keep them clean. Two geographers joined in the discussion and pointed out the importance of work of the kind described at the meeting for anyone who has to study man's place in Nature. Both put in a plea for more work of the same kind and also for meteorological records which could be made the basis of geographical science. At present the material supplied to them by the meteorological services gives no clue as to how a man would react under those conditions. In a final word, Prof. Glaser pointed out that any discussion of comfort must take into account the fact that what is comfortable for *A* is not comfortable for *B*, and that what is uncomfortable for *A* to-day may be quite comfortable for him in a few weeks time when he has become acclimatized. He also pointed out something much more striking, namely, that comfort can be achieved at an internal temperature relatively far removed from the person's 'normal' one; and as a last shot at the reliability of comfort as an index of any value, he directed attention to the fact that the man in a *rigor* from malaria with a rising temperature usually feels most miserably cold.

OBITUARIES

Prof. A. Sommerfeld, For.Mem.R.S.

THE death of Prof. Arnold Sommerfeld, at the age of eighty-three, occurred in Munich on April 26, after he had been knocked down by a motor-car.

With Sommerfeld one of the physicists has passed away who helped transform physics from what we now call classical physics to the new or quantum physics. "Quantum Theory is a child of the twentieth century", Sommerfeld was fond of saying, alluding to the fact that Planck introduced the quantum constant h in the theory of black-body radiation in 1900. Much of the rearing of this infant fell to Sommerfeld.

Sommerfeld's main contribution to quantum physics consists not of the fundamental laws or models. To his name there remains attached the fine structure constant and the method of applying quantization to more than one variable; the discovery of selection and intensity rules and thereby the interpretation and classification of a wealth of spectroscopic data in the optical and X-ray region; and the opening up of a new era in the theory of metals by his application of Fermi statistics to the electrons in metals. His main importance lies in his untiring probing into the new methods of atomic physics, by carrying problems to the ultimate test of quantitative agreement between experiment and theory. He was tireless in propounding the new theory at home and abroad in a spirit of optimism and enthusiasm; and no one has done so much for the consolidation of the rapidly developing new physics as he did by the five editions of "Atombau und Spektrallinien" which appeared between 1919 and 1931, each with many chapters re-written and brought up to date. Physicists all over the world have derived great profit from this labour, which seemed scarcely to interrupt the steady flow of research papers of Sommerfeld himself and his numerous pupils.

Sommerfeld was proud that he came from Königsberg, a geographical outpost and spiritual bastion among German universities. His father was a medical man, and the son graduated at the Gymnasium (1886) and University (1891) there. Franz Neumann, then ninety years old, who was the originator of the teaching of theoretical physics as a subject in its own rights and of the seminar method of teaching theoretical subjects, had made Königsberg one of the foremost schools for mathematics and mathematical physics. Sommerfeld's dissertation (under F. Lindemann), on "The Arbitrary Functions in Mathematical Physics", deals with the development of functions according to systems of orthogonal functions. Up to his death Sommerfeld found occasion to enlarge on this first brilliant work of his.

The full power and originality of Sommerfeld's mathematical construction appeared soon after in a series of papers on the diffraction of light by an edge (1894). The advance of this theory over previous ones (Fresnel, Kirchhoff) lies in defining the solution entirely by the differential equation of wave propagation together with the boundary conditions on the opaque half-plane; the method is an ingenious combination of image methods and of Riemannian multiply connected planes. In later years (1911), Sommerfeld extended the method when he discussed the diffraction of X-rays by deep wedge-shaped slits (Walter and Pohl) in papers that led to a reliable value of the then still unknown wave-length of X-rays.

In 1895 Sommerfeld became assistant to Liebisch in the Mineralogical Institute in Göttingen; but soon after he turned to more inspiring work than drawing crystals by becoming assistant to Felix Klein. This great master of mathematical synthesis deeply impressed Sommerfeld. Together they planned and carried out the writing of the four monumental volumes "Theorie des Kreisels" (1897–1910), in which the subject of gyroscopic motion is used as a theme for making evident the manifold connexions between dynamics and a variety of mathematical subjects.

The period in Göttingen ended in 1897, when Sommerfeld was appointed to his first chair, that of mathematics at the Bergakademie in Clausthal in the Harz Mountains, not far from Göttingen. The three years he spent there, newly married, were very happy ones.

His next appointment was the chair of applied mechanics at the Technische Hochschule, Aachen (1900–6). His contact with the engineering school turned his interest to applied subjects, even although he tackled problems of fundamental importance. The papers of this period, on viscous flow lubrication, on friction, on the beats between generators working on the same grid, are among those to which Sommerfeld liked to look back in a spirit of satisfaction not unlike that of Goethe's Faust when he speaks of the improvements he is bringing to the country by constructing canals and irrigation.

At the same time, the problems of ether physics were occupying Sommerfeld. The proper modes of vibration of a rigid spherical electron was a problem seriously discussed at that time, and Sommerfeld, like others, wrote highly mathematical papers on this subject, of which the last appeared in 1905, the year of the birth of relativity. Of more lasting importance are his studies of the electromagnetic fields which are emitted by the sudden stopping of a cathode ray, the *Bremsstrahlung* or white X-ray radiation according to the hypothesis formulated independently by Stokes, Liénard and Wiechert. This subject was followed up as, through the experiments of Barkla on the polarization of X-rays, more than mere total intensity data became available, and as similar effects were measured for gamma-rays. Later it appeared repeatedly in quantum form in papers by Sommerfeld's pupils.

Meanwhile, Sommerfeld had moved to Munich. It was Röntgen, the mighty man in the philosophical faculty, who insisted that Sommerfeld would be a worthy successor to Boltzmann in this chair that had been vacant for some time. A small but autonomous Institute for Theoretical Physics was connected with the chair. The workshop facilities and a few instruments made it possible to illustrate by simple experiments some of the conclusions arrived at in the theoretical courses. L. Hopf's work on Reynolds's number for flow in an experimental river-bed, and soon Laue, Friedrich and Knipping's discovery of X-ray diffraction by crystals, fully justified the existence of such an institute which had appeared to some as a self-contradiction.

In Munich Sommerfeld soon began to attract students in ever-growing numbers. P. Debye, whom he had brought with him from Aachen as his assistant, shared with Sommerfeld the success of building up a first group of graduate students who were keenly intent on physics and also enjoyed the colourful life which Munich offered by the combination of its natural and artistic climate. Many a problem was raised and discussed in the after-lunch meetings in the Hofgarten Café, between Sommerfeld and his group, the experimentalists from Röntgen's laboratory and those of the Technische Hochschule. These frequent informal meetings of physicists of various degrees of experience were most stimulating, even more so than the official colloquium which took place once a week during term-time.

Sommerfeld's success as a teacher was due to the clear and concrete expression of his ideas, and to the choice of subject in his lectures, which made even the young student realize that behind the domain of established theory there follows a domain of unsolved problems. The research on which he was currently engaged often occurred in preliminary form in Sommerfeld's course lectures; thus in 1909 the theory of relativity appeared in his electrodynamics course at a time when he was developing the four-dimensional vector form of this theory, and in 1927 the application of Fermi statistics to metals. This made his introduction to physical theory always an exciting experience full of reality. Further, Sommerfeld had a keen appreciation of intellectual capacity and real endeavour at whatever stage it appeared, and he was a friend, not only a teacher, to his students. He took them home and made them perform, or listen to, music or reading. In winter, skiing expeditions would be organized during week-ends or in the Easter vacations. On such occasions a long line of physicists might be seen making their way up the snowy slopes, and a panting discussion might be heard through the clean cold air of recent or future experiments and theories.

Among the problems of applied physics to which Sommerfeld and his pupils made essential contributions, that of the propagation of electric waves along the surface between two media stands foremost. His student days had been marked by the impact of Hertz's experiments on the theory of electromagnetism. In 1898 he gave a quantitative theory of Hertz's results on waves along wires; in 1911 his pupil Hondros discussed waves of all types travelling along dielectric rods. Starting in 1909, a series of papers dealt with the propagation of radio waves along an earth assumed flat or spherical, and with the directed action of horizontal antennæ (v. Hoerschelmann). Many years later, Sommerfeld gave a condensed account of this group of papers in Franck and Mises' book on partial differential equations in physics.

Regarding Sommerfeld's contributions to the development of atomic theory, the account can be short, because this is so much more recent work that it is still firmly imbedded in the memory of university teachers in many countries, who are handing on to the new generation their own personal impressions of Sommerfeld and his work, which they gained either at his school or in the course of his extended visits to other universities (Spain, 1922; United States, 1922–3; England, 1926; India, Japan, California, 1928–29; Volga congress, 1930; Ann Arbor, 1931). Sommerfeld's book "Atombau und Spektrallinien" has been, from 1919 on, an unfailing guide through the rapidly accumulating volume of atomic theory. In 1929 it was supplemented by the "Wellenmechanischer Ergänzungsband", which, some years later, was converted into a full-fledged companion volume "Wellenmechanik" (3rd edit., 1944). With the advent of wave-mechanics, theoretical atomic physics returned to the type of eigenvalue problems which had been Sommerfeld's favourite field from his early days on. No wonder that he impressed his personal stamp on the account of the new subject.

Among the major decisions in Sommerfeld's life were the refusals to accept the chairs of theoretical physics in Vienna (1917) and in Berlin (1927). He retired from the Munich chair in 1935, but continued intensive scientific activity up to the very last. The six volumes of "Vorlesungen über theoretische Physik" (the last of which is being prepared for publication) are, as he wrote, a bequest to the young generation; their preparation enabled him to survive the political chaos during his years of retirement. It is hard to believe that so vigorous and in many ways novel an account of classical physics should have been written by a man nearing, or even surpassing, his eightieth year. Two of the volumes have appeared in English translation, and the others are to follow shortly.

With his long list of scientific papers and his monumental books on atomic theory and on classical physics, Sommerfeld will always be regarded as an imposing figure standing on the threshold between two periods in the history of physics. As long as his pupils live, they will bear an affectionate memory of a great teacher and unselfish friend.

P. P. EWALD

Mr. Lincoln Ellsworth

LINCOLN ELLSWORTH, whose death took place at the end of May, was one of the pioneers of polar flying, both in the Arctic and the Antarctic. He was born in Chicago in 1880 and was employed for several years on survey work on Canadian railways, and also as an assistant engineer on goldfields in Alaska. During the First World War he was in the U.S. Army Air Corps.

Ellsworth first became known to a wider public in 1925, when his father decided to finance a flight which Roald Amundsen was planning to make to the north pole in Dornier-Wal flying boats. When near the pole it was found necessary to land on a lead of open water in the polar pack. The take-off, however, proved extremely difficult. One of the flying boats was abandoned, and it was three weeks before the other was again airborne and able to return to Spitsbergen from a farthest north latitude of 78° 44′.

Next year Ellsworth again collaborated with Amundsen, who was negotiating for the purchase of an Italian airship, renamed the *Norge*. Nobile was the technical expert, Amundsen provided the polar knowledge, and much of the financing again came from Ellsworth. The expedition was entirely successful. It took off from Kings Bay, Spitsbergen, on June 11, 1926, and after crossing the north pole landed at Teller in Alaska three days later.

Ellsworth's next effort was to assist Sir Hubert Wilkins in plans for a voyage in 1931 from Spitsbergen northwards under the pack-ice in the submarine *Nautilus*. He did not himself take part in the expedition, but was one of the party that same summer on the airship *Graf Zeppelin* on her Arctic voyage from Friedrichshafen over Franz Josef Land and Severnaya Zemlya (Nicholas II Land).

This first contact with Wilkins was the beginning of a long and intimate association, and Ellsworth now turned his attention to the Antarctic, with Wilkins as his adjutant. His first attempts, however, in 1933–34 at the Bay of Whales in the Ross Sea, and in 1934–35 from Snow Hill on the east coast of Graham Land, were unsuccessful; but next year, with Hollick-Kenyon as pilot in a Northrup machine, the *Polar Star*, a flight was made from Dundee Island on the north-east coast of Graham Land across Antarctica to the Ross Sea. No less than three landings were made, and the flight, which had begun on November 23, 1935, ended on December 4, when the machine landed on the Ross Barrier some miles inland from the Bay of Whales. Ellsworth's radio had failed at an early stage in the flight, and in view of the uncertainty arising the British, Australian and New Zealand Governments in collaboration decided to divert *Discovery II* from her usual oceanographical work. She arrived at the Bay of Whales on January 15 and rescued Ellsworth and his companion, who had been living in an ice cave for six weeks. This flight was the most successful yet made in the Antarctic, and the three landings to wait until the weather improved were a completely new departure in polar flying, representing a striking advance from Ellsworth's flying boat experience in 1925.

After his trans-continental flight, Ellsworth made one more expedition to the south, in 1938–39, when a flight was made over Princess Elizabeth Land at 12,000 ft. along the 79th meridian to 72° S. On his return, Ellsworth sold his ship *Wyatt Earp* to the Australian Government, having by now seen polar flying develop from the first uncertain stages to his own successful flight across the Antarctic continent.

J. M. WORDIE

Miss V. E. Beneš

VLASTA EVA BENEŠOVA was born in Kutna Hora, Bohemia, on December 2, 1919. She studied at the Lycée at Kolin and was a distinguished student in the Pharmaceutical Department of the University of Prague. After holding various provincial appointments she returned to Prague and began to carry out research work on "La sedimentation des Algues", under Prof. Silvestr Prat. In 1947, with the aid of a bursary, she proceeded to Paris and continued her research at the Sorbonne under Prof. W. Plantefol. She published three papers in the *Comptes rendus* of the Paris Academy of Sciences in 1948 and 1949, her work on *Hæmatococcus pluvialis* being an important contribution to our knowledge of the Volvocales. Afterwards, fired with enthusiasm by a visit to the marine station at Roscoff, she began a serious study of the marine algæ, under Prof. J. Feldmann and M. Chadefoud. In 1949 she sailed for Australia, where she collected marine algæ extensively on the coasts of New South Wales and made an intensive search for members of the Ceramiales with the view of a detailed study of their life-cycles. Despite her language difficulty she taught easily, and Prof. Burges writes of the active and successful contribution that she made to the study of the algæ in the University of Sydney. Towards the close of 1950, in a serious fall in the laboratory, she fractured her pelvis; but she made a good recovery and returned again to collect on the shores of New South Wales, a locality for which she had developed a deep regard. Perhaps it was too soon for her to venture alone on reefs as difficult as those near the Woy Woy Research Station, for to the dismay of her friends, on March 10 she did not return from the collecting ground.

Prof. Feldmann writes: "Sa tragique disparition qui est venue si soudainement interrompre sa carrière, constitue une perte sensible pour l'Algologie. Mais le souvenir de Vlasta demeurera surtout vivace dans le cœur de ceux qui l'ont connu et ont pu apprecier ses qualités d'esprit et de cœur." LILY NEWTON

WE regret to announce the following deaths:

Prof. J. W. Bigger, during 1924–50 professor of bacteriology and preventive medicine in the University of Dublin, aged fifty-nine.

Harald Blegvad, secretary-general of the International Council for the Exploration of the Sea, on August 22, aged sixty-five.

Brigadier E. M. Jack, C.B., C.M.G., director-general during 1922–30 of the Ordnance Survey, on August 10, aged seventy-eight.

Dr. John R. Loofbourow, associate professor in the Massachusetts Institute of Technology, known for his work on absorption spectroscopy and the biological effects of radiation, on January 23, aged forty-seven.

NEWS and VIEWS

National Science Foundation : Dr. Harry C. Kelly

The second of the technical divisions of the National Science Foundation, 901 16th Street, N.W., Washington, D.C., has been established with the appointment of Dr. Harry C. Kelly as assistant director for the Division of Scientific Personnel and Education. The Division of Biological Sciences was the first of the four statutory divisions to be established. The Division of Scientific Personnel and Education will be responsible for the development and administration of programmes relating to the granting of scholarships and fellowships by the Foundation in the mathematical, physical, biological, engineering, and other sciences. Until recently, Dr. Kelly was head of the Scientific Section of the Office of Naval Research Branch Office in Chicago. Previously he was chief of the Scientific and Technical Division which advised General Douglas MacArthur on the development of a scientific and technical programme for Japan. Under his leadership, Japanese scientific men elected a representative body to reorganize and rehabilitate their national bodies of science. These activities led to a new Science Council, democratically elected by qualified men of science.

Nuffield Foundation Grants to the University of Cambridge

The Nuffield Foundation has made a grant of £25,000 over a period of five years for the development of calculating machines in the Mathematical Laboratory, University of Cambridge, under the direction of Mr. M. V. Wilkes. This Laboratory has already built a high-speed electronic calculating machine (the Edsac) and applied it in a number of fields of scientific research. It has become evident that there are many opportunities in Cambridge for such applications, and the present machine is already overloaded. The Foundation's grant is to be used for the construction of a new machine, which will be more reliable than the present one, slightly faster, contain more storage capacity and be able to handle a much larger quantity of work. The general design of the new machine is already clear and a certain amount of preliminary work has been undertaken. The Foundation has also made a grant of £5,000 over a period of five years for the support of "theoretical studies in biochemistry" to be carried out in the Chemical Laboratory under the direction of Sir John Lennard-Jones. Of this grant £4,400 is to be used for the salary of a senior assistant, whose duties will be to pursue research in subjects likely to be of value in biochemistry and to supervise the work of research students in the same field, and the remaining £600 for incidental expenses. The programme of work is the outcome of recent studies in Sir John Lennard-Jones's Department, the immediate purpose of which was to discover the principal factors which determine the shapes of molecules. This has led to the new views of the significance of 'lone pairs' of electrons, and of the so-called 'hydrogen bond' or the 'hydrogen bridge' of molecules of biological interest. Theory alone cannot be expected to unravel the problems of complex molecules such as proteins, but it may help in choosing between some of the models which have been proposed. These, and other similar problems, require for their solution not only experts in biochemistry, chemistry and physics, but also others with a good training in mathematics and theoretical chemistry.

The Peckham Health Centre

It is with regret that we note the closing down of the Peckham Health Centre. In a statement prepared by the directors of this pioneer health centre they indicate that an approach to the Ministry of Health disclosed that in principle Peckham was deemed to be contrary to the policy of the Ministry. It could not receive support from the Health Act because it could not be fitted into the existing administrative scheme for the following reasons : the health centre has been concerned exclusively with the study and cultivation of health and not with the treatment of diseases ; it is based exclusively on the integrated family and not on the individual ; it is based on a "locality" and has no "open" doors ; the basis is contributory and not free. The directors also state that Peckham has been based on autonomous administration and so does not conform to the lines of administration laid down by the Ministry. Moreover, Peckham arises out of an original conception which extends into a region beyond the ambit of present-day medicine and hygiene and so is not eligible to receive the enabling stamp of authority. The building has now passed into the control of the London County Council, which proposes to use it for other purposes.

Mechanism and Evaluation of Antiseptics

A conference which meets to discuss the mechanism and evaluation of antiseptics must necessarily cover a wide field, and this is evident in the eighteen papers to be found in "Mechanism and Evaluation of Antiseptics" (*Ann. New York Acad. Sci.*, 53, Art. 1, 219 ; 1950 ; 3 dollars), which prints the papers given at a conference held in 1949. It is impossible in a short space to indicate the contents of so many papers ; they discuss streptomycin and other antibiotics, the procedure of paper-disk assay, the meaning of bacteriostasis, bactericidal effect and rate of disinfection, the interaction of surface-active agents and proteins, the role of antagonisms in the evaluation of antiseptics, present trends in the methods of testing antiseptics, the mode of action of halogens, and kindred subjects. The bibliographies attached to each paper extend the usefulness of a volume which will interest everyone concerned with the control of injurious organisms.

Foremanship Training in Technical Colleges

On all sides of industry there is evidence of the increasing recognition of the vital role of the foreman in modern management. Broader study of the job, improved selection, and extensive training schemes are developments which are now prominent features in many industrial organizations. Yet there are still large areas where little has been done, and this problem has recently been considered by the British Institute of Management. A sub-committee was set up which, in its report, suggests practical ways in which technical colleges may give immediate help in the training of foremen ; its recommendations are based on comprehensive evidence of the needs of industry and modern methods of meeting them. The sub-committee indicates that it is only concerned with short-term programmes designed to appeal to the established foreman and that, though such brief courses may be a useful introduction, they are no substitute for progressive long-term training within industry and outside. No recommendations were made about the means of training potential foremen or the contribution of the technical colleges to the long-term training arrangements of the small firms, and these are matters deserving further and urgent study. Copies of the report may be obtained from the British Institute of Management, 8 Hill Street, London, W.1.

Society for the Bibliography of Natural History

INSTITUTED for the study of the bibliography of all branches of zoology, botany and geology, the most recent issue of the *Journal of the Society for the Bibliography of Natural History* contains a detailed list of the published writings of C. J. Maynard (1845–1929) by Charles Foster Batchelder (2, No. 7; Jan. 1951). Maynard spent most of his life on a small farm at Newton, Massachusetts. He had little formal education and at first worked on the family farm. Soon he took up taxidermy, and through this managed to eke out a frugal existence while making valuable contributions to knowledge of the natural history of his birthplace and two districts which he visited frequently—Florida and the Bahamas. Altogether Maynard published more than 250 books and papers, many of them bearing the imprint of a very unconventional and original man. With some of his more important works Maynard took pride in setting the type, making wood-cuts, drawing lithographs and doing all the press work himself. He also issued price lists of natural history specimens which he had for sale, and, much to the horror of many orthodox taxonomists, more than once chose such lists to describe new species.

Radio Communication and Radio Measuring Instruments Committee

A JOINT Committee, to be known as the Joint Advisory Committee on Radio Communication and Radar Measuring Instruments, has been set up from representatives of three trade associations—the Radio Communication and Electronic Engineering Association, the Radio and Electronic Component Manufacturers Federation and the Scientific Instrument Manufacturers Association. The Committee is open to all members of these associations; it is not itself, however, a trade association, but rather an advisory body for all matters relating to the development and production of radio-communication and radar-measuring instruments. In particular, it is expected that the provision of this single channel for consultation with Government departments on matters of common interest in this field of measuring instruments will prove convenient both to the industry and to the departments. The secretary of the Committee is the assistant secretary of the Radio Communication and Electronic Engineering Association, which is at 59 Russell Square, London, W.C.1.

International Congress on Analytical Chemistry, 1952

FURTHER details are now available concerning the arrangements for the International Congress on Analytical Chemistry which is to be held in Great Britain next year. The Congress will meet at Oxford during September 4–9. Papers will be issued in advance of the meeting and the contributors will give only a brief summary of their papers, most of the time being given over to discussion. Arrangements have been made to publish the whole of the proceedings in a special number, or numbers, of *The Analyst* as soon as possible after the Congress. During the Congress it is proposed to have in operation working demonstrations illustrating new techniques or special applications of older techniques in analytical chemistry. In addition to this, and quite separate from it, there will be a trade exhibition comprising apparatus and books. This exhibition will be under the management of Mr. W. Thompson, of the Imperial College of Science and Technology, London, S.W.7. The honorary secretary of the Congress is Mr. R. C. Chirnside, Research Laboratories, General Electric Co., Ltd., Wembley.

Colonial Service: Recent Appointments

THE following appointments in the Colonial Service have recently been announced: S. M. Taylor (agricultural officer, Sierra Leone), director of commerce and industry, Sierra Leone; A. E. Trotman (director of agriculture, Jamaica), member for agriculture and natural resources, Tanganyika; J. J. Lawrie (assistant conservator of forests, Gold Coast), assistant conservator of forests, Somaliland Protectorate; W. D. Burrowes (agricultural economist, Jamaica), senior agricultural economist, Jamaica; L. A. Powell (agricultural officer, Jamaica), senior agricultural officer, Jamaica; D. N. Smalley (senior agricultural assistant, Nyasaland), principal agricultural assistant, Nyasaland; G. Moore, agricultural officer, Gold Coast; G. P. Leedal, geologist, Tanganyika; G. F. Burnett, scientific officer (entomologist), Colonial Insecticides Research Unit, Tanganyika; J. F. Garden, veterinary officer, Tanganyika; R. C. Nixon, veterinary officer, Tanganyika; G. Y. Benzies, assistant meteorologist, Nigeria; J. F. Fisher, meteorological officer, Nyasaland; E. H. Holland, veterinary officer, North Borneo; M. A. Prentice, entomologist, Uganda.

City and Guilds of London Institute

MR. J. W. VOELCKER has been appointed secretary of the City and Guilds of London Institute for the Advancement of Technical Education in succession to Mr. G. C. Stephenson, who has retired, but who will continue to help and advise in the work of the Institute. Mr. Stephenson has been secretary of the Institute since 1924. Mr. Voelcker studied electrical engineering during 1920–22 at the City and Guilds College, and then he went to the Massachusetts Institute of Technology. He joined the English Electric Co., Ltd., in 1925. Mr. Voelcker is the general editor of *The Central*, the journal of old students of the City and Guilds and Finsbury Technical Colleges, and president of the M.I.T. Club of Great Britain.

University of London: Appointments

THE following appointments in the University of London have been announced: Mr. W. B. Emery, to the Edwards chair of Egyptology tenable at University College, from October 1, or as soon after as possible; Dr. E. Glaister, to the University readership in mechanical engineering tenable at the Imperial College of Science and Technology, from October 1; Mr. T. W. Hutchison, and Mr. R. Turvey, to University readerships in economics tenable at the London School of Economics and Political

Science, from October 1. The title of professor of veterinary anatomy in the University has been conferred on Mr. James McCunn, in respect of the post held by him at the Royal Veterinary College.

The Night Sky in September

New moon occurs on Sept. 1d. 12h. 49m. U.T., and full moon on Sept. 15d. 12h. 38m. The following conjunctions with the moon take place: Sept. 3d. 13h., Saturn 5° N.; Sept. 17d. 02h., Jupiter 5° S.; Sept. 27d. 21h., Mars 0·02° S.; Sept. 28d. 05h., Venus 7° S. In addition to these conjunctions with the moon, Mercury is in conjunction with Venus on Sept. 12d. 13h., Mercury being 8·3° N. Mercury is too close to the sun during the early part of September to be seen; at the middle and end of the month it rises at 4h. and 5h. respectively, and may be seen for a short period before it is lost in the sunlight. Venus is in inferior conjunction on Sept. 3, but later in the month can be seen in the morning hours, rising at 4h. 05m., and 3h. 10m., on Sept. 15 and 30, respectively. The crescent form of the planet is easily seen with small optical aid and the stellar magnitude varies between $-3 \cdot 3$ and $-4 \cdot 2$ during the month. Mars, a morning star, rises about 2h. 15m. throughout September; towards the end of the month the planet is very close to α Leonis. Jupiter rises at 19h. 55m., 19h., and 17h. 55m., at the beginning, middle and end of the month, respectively, stellar magnitude $-2 \cdot 5$. Saturn is in conjunction with the sun on Sept. 29 and is too close to the sun during the month for favourable observation. Autumnal equinox occurs on Sept. 23d. 21h. Occultations of stars brighter than magnitude 6 are as follows: Sept. 13d. 19h. 23·6m., ι Aquar. (*D*); Sept. 22d. 23h. 49·2m., 136 Taur. (*D*); Sept. 23d. 0h. 16·2m., 136 Taur. (*R*). (*D*) and (*R*) refer to disappearance and reappearance, respectively, and the times refer to observations made at Greenwich. On Sept. 1 an annular eclipse of the sun takes place and is visible as a partial eclipse at Greenwich, where it begins at 11h. 20m. and ends at 12h. 53m. The magnitude of the eclipse at Greenwich is 0·16, and the greatest phase is attained at 12h. 07m.

Announcements

Lieut.-General Sir Frederick Morgan has been appointed Controller of Atomic Energy in succession to Lord Portal of Hungerford.

Mr. Vernon Harbord, a consulting metallurgist and a partner of the firm of Messrs. Riley, Harbord and Law, has been elected president of the Institution of Mining and Metallurgy for the session 1952–53. Mr. Harbord is a past student of the Royal School of Mines. During the Second World War he was a metallurgical adviser to the Armament Research Department. He has served on the council of the Institution since 1940, being vice-president during 1947–50.

The seventh Dalton Lecture will be delivered by Lord McGowan in the Manchester Town Hall on September 27, at 7 p.m. Lord McGowan will speak on "A Hundred Years of Chemistry" The lecture is open to the public, but admission is by ticket, obtainable free from the Honorary Secretary, Arthur Carroll, 9 Central Avenue, Sale, Manchester. Supporting the 1951 Dalton Lecture, there will be an exhibition illustrating the progress of chemistry on September 27 (10 a.m.–9.30 p.m.) and September 28 (10 a.m.–8.30 p.m.) in the Gas Showrooms Basement, Town Hall Extensions, Mount Street, Manchester. Admission is free.

A conference on "The Rheology of Films and Surfaces" has been arranged by the British Society of Rheology, jointly with the local branch of the Chemical Society, at the Washington Singer Laboratories, University College, Exeter, and will be held during September 27–29. Further particulars can be obtained from the honorary secretary of the British Society of Rheology, Dr. E. W. J. Mardles, Royal Aircraft Establishment, Farnborough, Hants.

The Second International Congress on Astronautics is to be held in the Caxton Hall, London, S.W.1, during September 3–8. The Congress will be in two parts, the first (September 3–5) being for delegates only, when the business discussed will include the inauguration of an International Astronautical Federation. The second part (September 6–7) will be open to the public, and will consist of the presentation of technical papers.. Further particulars can be obtained from the Secretary of the British Inter-planetary Society, 157 Friary Road, London, S.E.15.

The ninth annual meeting of the Electron Microscope Society of America will be held in the Franklin Institute, Philadelphia, Pennsylvania, during November 8–10. Besides contributed papers, and an exhibit of electron micrographs and commercial exhibits, there will be a symposium on "Elementary Electron Optics and Factors effecting the Electron Microscopical Image". Programmes and abstracts will be available from T. G. Rochow, American Cyanamid Company, Stamford, Connecticut; information regarding local arrangements can be obtained from D. D. Pendleton, Radio Corporation of America, Camden 2, New Jersey.

A joint meeting lasting about a week of Commissions 2 (Soil Chemistry) and 4 (Soil Fertility and Plant Nutrition) of the International Society of Soil Science will be held in Ireland in 1952, probably during July. The main purpose of this meeting will be to examine and discuss the application of soil science to the solution of farming problems through the medium of soil analysis, field experiments and other branches of soil research. All papers will be printed in advance, and those desiring to submit papers are requested to consider preparing them in the near future. All communications should be addressed to the secretary of the Department of Agriculture, Dublin, and marked 'International Society of Soil Science Meeting'.

The eleventh series of postgraduate lectures organized by the Oil and Colour Chemists' Association will be given by Dr. H. W. Thompson, of the University of Oxford, in the Lecture Theatre of the Royal Institution, 21 Albemarle Street, London, W.1, at 6.30 p.m., on October 11, 18 and 25. Dr. Thompson will speak on "Molecular Dynamics and Chemicals Problems". The lectures are open to all on payment of a fee of 10*s.*; application should be made to the general secretary of the Oil and Colour Chemists' Association, Memorial Hall, Farringdon Street, London, E.C.4.

CURRENT TRENDS IN OCCUPATIONAL PSYCHOLOGY

A DISCUSSION on "Current Trends in Occupational Psychology" occupied the morning session on August 10 of Section J (Psychology) of the British Association. The first contributor was Dr. C. B. Frisby, director of the National Institute of Industrial Psychology. Dr. Frisby began by tracing the development of industrial psychology in Britain during the past thirty years. For most of this period, emphasis had been laid on the investigation of capacities rather than inclinations, and on the use of laboratory methods of inquiry. The Hawthorne studies, and fuller employment, had then caused attention to become focused on conditions affecting motivation at work. In consequence, the industrial psychologist had had to devote more of his time to field investigations; and these had produced new methodological problems.

Dr. Frisby illustrated his contentions by references to three post-war inquiries carried out by the National Institute of Industrial Psychology. One was into joint consultation. It was a study of current practice, and an attempt to identify factors apparently associated with successful joint consultation. The second was designed chiefly to survey current practice in regard to the status, selection and training of supervisors in industry; but was aimed in addition at the improvement of existing selection and training procedures. The object of the third investigation was to discover principles governing the determination of optimum units of work in repetitive tasks that had been greatly subdivided. "It is clear that at some point in the breaking-down process, for a variety of reasons, the operative will become less effective than he was with the larger task. The problem was how to give some guidance to the production engineer in identifying this point."

All three investigations demonstrated the need for sound means of assessing attitudes to work and satisfactions derived from working conditions; and a basic methodological problem was that of finding ways of doing this which would be adequate and acceptable but not time-consuming. Dr. Frisby said that attitude scales have possibilities that should be more thoroughly explored in Britain; but that the interview is usually to be preferred, and interviewing skill is of great importance to the industrial psychologist. Other problems thrown up by the three researches centred on consideration of criteria of occupational success, the most difficult—and perhaps the most important—of all the tasks facing the occupational psychologist.

Dr. N. A. B. Wilson, senior psychologist to the Admiralty, read a paper—part of which was heard by H.R.H. the Duke of Edinburgh—on "Applications of Psychology in the Defence Departments". Psychologists, he said, can scarcely be expected to abolish war. So far, with the possible exception of a few psychiatrists, they have not even proved very good at what is called psychological warfare, which is the art of winning wars without actually fighting, or basic warriorship. The activities of psychologists in the Defence Departments can, in fact, be grouped under two main headings: fitting the man to the job, and fitting the job to the man. In the first group are to be found problems arising in the improvement of methods of personnel selection, methods of training and examining (for example, aircraft pilots), and documentation (for example, at recruiting centres). In the second are problems arising in the improvement of methods of work (for example, gun drills), design and layout of equipment (such as aircraft cockpits), and living and working conditions (for example, operating conditions in extremes of climate). In the Admiralty, the Naval Motion Study Unit, which is the joint responsibility of the Director of Operational Research and the Senior Psychologist, has made proposals that would reduce by two the size of a gun-crew. The psychologist's contributions in this field were of two kinds. He advised on the design of experiments and on the criteria needed in the evaluation of proposed changes; and he advised on the needs and capacities of operators of equipment. His aim was to help to ensure that all drills and equipment prepared for Service use show the maximum possible adaptation to the needs and capacities of all probable users in all probable operational circumstances.

Dr. Wilson commented on five topics that seem likely to provide much work for military psychologists. First, man-power planning in terms of quality is now becoming possible. Given the composition of a naval entry in terms of classification test scores, and given a fairly stable connexion between those scores and advancement, useful estimates can be made of the petty officer material—judged by present standards—likely to be available in a few years time. Secondly, more consideration is being given to the utilization of marginal groups, including the very able or unusually qualified; the dull; the physically substandard; 'high-grade funnies'; and the unstable. Thirdly, within the Services there are many organizational arrangements that would repay investigation in the light of what we now know about human abilities and interests. Fourthly, the educative function of Service psychologists should be developed. For example, they could profitably make better known the advantages of 'over-learning' skills and providing trainees with knowledge of their own progress in training; and of the proper co-ordination of control adjustments with related display changes in equipment design. There is also a need for the further *ad hoc* training of personnel selection officers to give day-to-day advice on matters, falling within their sphere, which the Service psychologists have no opportunity of considering, and for the provision of information, for the ordinary man in the tank or ship or aircraft, on the uses of applied psychology in warfare. Fifthly, it is becoming evident that there is a place for the discreet use of attitude and opinion surveys in the personnel work of the Services. Dr. Wilson concluded his paper, which was very well received, by directing attention to the need of the Services for psychologists who are competent theoretical men and methodologists.

A paper prepared by Dr. E. Anstey, head of the Civil Service Commission Research Unit, on "Applications of Psychology in the Civil Departments", was read by Mr. D. McMahon. It was concerned chiefly with the work of psychologists employed by the Civil Service Commission, either on the Civil Service Selection Board or in the Research Unit; but towards its close, passing reference was made to the place of psychologists on the Prison Commission and elsewhere.

Psychologists have made three distinctive contributions to the Civil Service Selection Board: first, in the planning of the work of the Board; secondly, in bringing to its activities a certain quality of expert knowledge in the scientific study of personality; and thirdly, in insisting from the outset on the need for a well-designed follow-up scheme, from which an objective judgment of the value of the board's procedures could be obtained. The last of these contributions, Dr. Anstey believes, is the most important; and the outcome will be a series of reports, the first of which has already appeared.

The main activities of the Research Unit have been job analysis, test construction and follow-up. The follow-up has included an inquiry into the progress of a hundred entrants to the Administrative Class who, being already employed in the Civil Service, did not go through the Civil Service Selection Board procedure. They had been given instead a more conventional written examination and board interview, though the board interview had been preceded by a private interview. The whole selection procedure had proved satisfactorily valid, when judged two years later by an overall grading of present performance; and the written examination alone had been found to have made a very useful contribution.

Dr. Anstey thinks that the time is ripe for psychologists in the Civil Service Commission to devote more time to discovering how to get the best out of people who have been selected. The incentives problem is of even greater importance in the Civil Service than in private industry. He wants to see more research done on the size and internal organization of the 'working group'; and on what he calls 'internal incentives', which would help individuals to make regular self-assessments of the quality and quantity of their work. He urged psychologists in the Civil departments to be clear in their own minds about the worthwhileness of their research projects before embarking on them; to make their reports intelligible to non-technical readers; and to aim at striking a satisfactory balance between a high professional standard and practical effectiveness.

Mr. Alec Rodger, reader in psychology at Birkbeck College, University of London, and consulting psychologist to the Admiralty and to the Central Youth Employment Executive, contributed a paper on "Vocational Guidance in Britain", in which he reviewed the past and present work of psychologists in this field and outlined several urgent problems. Conditions for research and development are now more favourable than they have ever been before, partly because the increasing need for the proper use of human resources in industry has directed attention to the advantages of sound guidance. This is shown in the new orientation of the Youth Employment Service and in the work of the Ministry of Labour's Industrial Rehabilitation Units: in both, psychologists have a small but important place.

The most pressing need of all, Mr. Rodger said, is for the clarification of our concepts of occupational success and failure, for without this we shall continue to lack satisfactory criteria whereby to judge the worth of much of our other scientific and technological work. A second need is for better ways of studying the 'requirements' of occupations. Here we have been too long content with the listing of ill-defined qualities that have been considered, on the basis of 'hunch', to be important. Empirical investigation is wanted, and it may well be founded provisionally on the notion that the best way to arrive at satisfactory conclusions about the requirements of an occupation is to study people who are acknowledged failures in it, and to compare them with people who are acknowledged successes. Thirdly, there is a need for a better functional classification of occupations. The conventional grouping of them, as concerned with ideas or things or people, is inadequate.

These papers seem to indicate clearly that occupational psychologists in Britain are in considerably better intellectual health than they were in the years immediately before the War. In research and development alike, they are making substantial strides in industry and in the Service and Civil departments. The work of the Service departments is perhaps particularly impressive in its range and quality. The papers read at this discussion are to be published in book form by Messrs Methuen and Co., Ltd.

TREND OF INORGANIC AND PHYSICAL CHEMISTRY SINCE 1850*

THE development of inorganic and physical chemistry during the past hundred years falls into two periods. Until the end of the nineteenth century these two branches of chemistry experienced a steady evolution, while their theoretical foundations, laid at the beginning of modern chemistry, remained unaltered; but about 1900 a revolution set in which changed these very foundations. The difference is as great as the contrast between the quiet security and constant progress of the Victorian age and the upheaval caused in this century by the two World Wars.

One of the greatest achievements during the first period was the discovery of the Periodic Law; it was based on Lavoisier's conception of the chemical element and on the atomic theory founded by Higgins and Dalton. No explanation for the Periodic Law could be given, and fantastic representations without scientific meaning were common; some unfortunate examples of this attitude can still be seen in the science exhibitions of London's Festival of Britain. A real understanding of the Periodic System only became possible after insight into the structure of matter had been gained, mainly as a consequence of the study of radioactive elements and their radiations. Radium was discovered by Pierre and Marie Curie in 1898, the theory of radioactive disintegrations developed by Rutherford and Soddy in 1902. From this work and from the discovery of isotopy in 1913 by Soddy, J. J. Thomson and Aston, three very important facts emerged which were in contradiction with the doctrines of classical chemistry: (1) elements are not immutable; (2) atoms are complicated structures containing a tremendous store of energy; (3) atomic weights are not fundamental constants. The recognition of these facts, and great strides made during the same period in experimental and theoretical physics, made it possible for Rutherford and Bohr to crown the old atomic theory by a theory of the atom. According to this theory the chemical character of

* Substance of a paper by Prof. F. A. Paneth, F.R.S., read on August 9 before Section B of the British Association meeting at Edinburgh.

an atom is determined primarily by the electric charge of the nucleus, not by its weight; atoms of different weight may belong to the same chemical element (isotopes), and atoms of the same weight to different elements (isobars). In this respect modern chemistry is nearer to Higgins's views than to the narrower ones of Dalton.

The advances made in the understanding of the nature of chemical atoms and of their mutual relationship were not only of theoretical interest. The study of the naturally occurring radioactive substances was followed by the artificial disruption of stable atoms, by the production of radioactive isotopes of inactive elements, and—most spectacular of all—by the creation of no less than nine chemical elements which are not to be found on our earth and of which one, plutonium, is the most important source of atomic energy.

The theory of the atom was also able to shed light on the question of chemical forces; in classical chemistry they were considered as something quite different from the forces dealt with in physics, and scarcely capable of further explanation. As atoms are now known to be structures built up of electrically charged particles, the combination of atoms to molecules is to be understood as the consequence of electric forces. All valency bonds are essentially electrostatic in nature, although the mechanism of interaction is different in the two cases of electrovalency and covalency. The exact mathematical treatment is difficult except in the simplest cases, but the possibility of explaining, in principle, all the so-called chemical forces by the laws known to physics can no longer be doubted.

The theory of chemistry is now a part of physics; but it must not be forgotten that many of the greatest advances in physics have been made on the basis of chemical discoveries. It is safe to predict that for a long time to come the deductive methods of theoretical physics will be supplemented by the inductive approach of the chemist.

IMPROVEMENTS IN CATHODE-RAY TUBE STORAGE: APPLICATION TO A PARALLEL TYPE OF DIGITAL COMPUTER

By G. H. PERRY

Telecommunications Research Establishment, Great Malvern

In recent publications[1-4], Prof. F. C. Williams and Dr. T. Kilburn describe a storage system for use with binary digital computers, using electrostatic charges on the fluorescent screen of a cathode-ray tube. In these papers, three possible forms of charge distribution are described, each having two states to represent the binary digits nought and one. These have been named: (*a*) dot–dash; (*b*) defocus–focus; (*c*) anticipation. The first of these has been described in detail and has been put into operation in the serial computer in the University of Manchester. In a parallel-operated computer all the digits of a number are used simultaneously, and hence its storage requirements are different from those in a serial machine.

Suppose we have a serial machine using n cathode-ray tubes; a number, of n digits, is stored at n points of a single line on a tube which is scanned serially. Adjacent lines store different numbers. If there are also n lines, and one number is required continuously in a computation, then its line will be regenerated n times compared with its neighbour, and this ratio will determine interaction and consequent spacing.

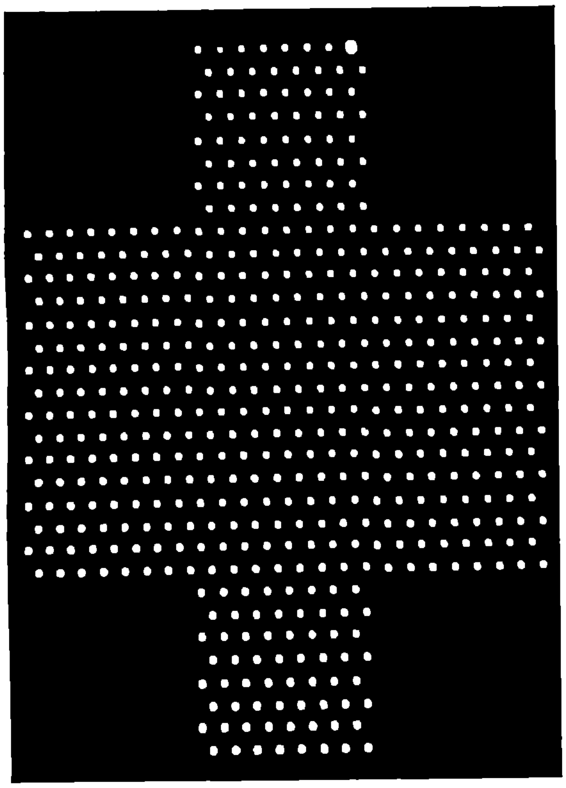
In a parallel machine of the same total capacity of n^2 digits in n cathode-ray tubes, a single number will be stored at n corresponding points on the n tubes. Again, if this number is required continuously, then each of its points will be regenerated n^2 times compared with its neighbour. It will be seen how much more serious is the interaction problem than in a serial machine.

When applying cathode-ray tube storage to the parallel computer now being built at the Telecommunications Research Establishment, Malvern, the dot–dash system was found to have several undesirable features. Although these features are all related, they may be considered under three main headings: (1) the interaction between elements of the store was such that the number of digits per cathode-ray tube had to be reduced to a point where it became impracticable for the requirements of a computer; (2) spurious signals due to imperfections of the fluorescent screen made selection of cathode-ray tubes necessary; with a high rejection-rate this was a costly process, and even then final anode voltages had to be limited to the order of 1 kV. in order to minimize these spurious signals; (3) the system was found to be extremely sensitive to variations of the deflexion voltages; even microphony of the valves producing the deflexion voltages could change the stored information.

Using the existing cathode-ray tubes, interaction could be reduced in two main ways: (*a*) reducing the net beam current; (*b*) increasing the final anode voltage of the cathode-ray tube, thus obtaining a finer-focused spot, and using a different portion of the secondary emission characteristics of the fluorescent screen.

A reduction in the net beam-current by about 20 per cent was first obtained by using what may be called a 'double dot' system, where the charge was re-established by a second dot placed a critical distance from the first. The refilling action of this system is slightly more efficient than the dot–dash method. Regarding final anode voltage, experiments showed that an increase reduced the interaction at the expense of signal strength; for example, an increase from 1 to 1·5 kV. enabled the separation between digits to be reduced from 1·8 mm. to 0·8 mm. for the same degree of interaction. This represents a fourfold increase in digits per unit area.

For about two years attempts have been made to manufacture cathode-ray tubes with screens which are free from storage imperfection; but so far as is known at the moment, no consistent results have been obtained. The majority of the imperfections were small compared with the cathode-ray tube spot, the diameter of which was 0·5 mm. In an effort to overcome their effect, the cathode-ray tube beam was modulated at 5 Mc./sec. at right angles to the line of the double dot. For six cathode-ray tubes tested, it was found that an amplitude of only 0·5 mm. was sufficient to make them work with a final anode voltage of 1·5 kV. All these tubes previously had only been satisfactory at 1 kV. A single cathode-ray tube store was now constructed



Crown copyright reserved

with 256 digits using the above techniques. This was used in conjunction with an experimental portion of the computer.

On further consideration, however, the defocus–focus system appeared to have many advantages over the modulation system. These are: (1) the refilling process by means of the focused central dot is much more efficient than that using a displaced dot, being effected by electrons emitted in all directions, instead of by those emitted only in a particular sector; as a result, the net beam current may be reduced with a consequent reduction of interaction; (2) since the defocused inspection spot and the focused refilling spot are concentric, the chances that the charge barrier due to an impurity of the screen would prevent the re-establishment of the charge are very slight; (3) the charge of the digit is detected by a defocused spot, and the system is therefore less sensitive to errors of the deflexion voltage than when using a focused beam; (4) there should be an improvement in signal strength due to the increased quantity of charge in the defocused spot.

Experiments have confirmed these advantages. The duration of re-filling pulses can be reduced to 0·8 μsec. compared with about 2 μsec. with the double-dot system, and the total time for reading or writing a digit can be reduced to 2 μsec.

Many cathode-ray tubes have been tested to determine the effects of impurities on the screen, and all have proved completely satisfactory. One in particular, which had at least six large impurities and had been rejected for use in a dot–dash store at 1 kV., was found to be perfectly satisfactory in a defocus–focus system at 2 kV. No variation in signal strengths could be detected larger than those normally obtained due to the variation of screen surface.

Trouble previously experienced due to the microphony of the deflexion valves completely disappeared; consequently, reliability has increased and the stability requirements of the deflexion voltages have decreased.

The increased signal strength due to the increased charge per digit of the defocus–focus system tends to compensate for the reduction of signal due to the increase of final anode voltage, and satisfactory signal/noise ratios are still obtained with 2 kV. final anode voltage. An experimental cathode-ray tube store of 512 digits using the defocus-focus system has been functioning for about six months. Each storage element may have had at least 256 regenerations adjacent to it before being itself regenerated. This is the maximum requirement, provided instructions and numbers are used alternately and are stored in different areas of the cathode-ray tube. The digits are arranged with 2·5-mm. separation in a pattern as in the accompanying illustration.

The electrical and mechanical design of the store has been completed, and a prototype to this design tested. The twenty stores required for the computer are now in process of construction.

Experiments have also been carried out to determine whether this system is suitable for serial storage. It has been found that a square pattern of 1,024 digits can be stored, and that any digit may have its neighbours brightened-up at least 64 times before being itself regenerated.

The cathode-ray tubes used in the above work were of type *VCRX* 266. This is a convenient type of 6-in. tube with low beam current and small spot diameter. All those tested were found suitable for defocus–focus storage without the need of selection.

I wish to thank members of the Research Laboratory of the General Electric Co., Ltd., for their co-operation in the development of experimental cathode-ray tubes, and the Chief Scientist of the Ministry of Supply for permission to publish this communication. [April 18.

ABILITY OF BIRDS TO COUNT

THE masters of 'clever' horses and dogs are often sincere in their belief that their pets really display intelligence of the highest order; for they are quite unable to imagine that the animals can really perceive small involuntary signs and signals which tell them when the right answer has been reached and hence when they must stop barking or stamping, as the case may be. Yet it is now quite certain that that is precisely what these 'clever' animals are doing. It was not the stallion "Zarif" of Elberfeld which reproduced Descartes's "*cogito ergo sum*" in ill-spelt German, nor was it the dachshund "Kuno" which answered the professor's question as to what creed he had with the words "Mine is yours". These 'clever' animals only obey their master's signs which, given at the proper moment, stop the barking or stamping by which they spell out their answers in code.

In a recent article (*Bull. Animal Behaviour*, No. 9; March 1951) Prof. O. Koehler states that the achievements of certain birds with which he has experimented are examples of true learning and in no way dependent on clues, voluntary or involuntary, given by the experimenters.

During training and 'spontaneous' experiments the observer and the bird were always separated by a partition so that the experimenter was never seen by the bird; while at work he was able to watch it through the view-finder of a cine-camera fitted into the wall. Moreover, when a deterrent was required in conditioning, only one degree of punishment was used and this was always the same. It was thus impossible for the experimenter inadvertently to give signs by means of the punishing apparatus since the latter functioned along all-or-none lines.

Unlike circus animals, Prof. Koehler's birds were sometimes left entirely to themselves and the results recorded automatically so that all possibility of clues from the investigator was ruled out. The birds learned many tasks without any punishment and merely by self-conditioning. Often spontaneous experiments were made by the birds in the complete absence of any human being. The birds were often left alone with their task while the experimenter was kept far away so that even possible telepathic connexion between man and animal could be excluded. Nearly all the problems solved by the birds in spontaneous experiments were recorded automatically by film for later study.

Not even the cleverest of the birds showed inborn capacities like human beings; but they did learn unnamed numbers which were presented to them by two principal methods: (1) simultaneous presentation, and (2) successive presentation. The first of these abilities is that of being able to compare groups of units presented simultaneously side by side by seeing numbers of those units only, excluding all other clues. This problem was presented to birds in quite different ways, starting with only two groups of edible units (grains of corn, fruit, pieces of meat, etc.), the two groups differing by one unit only, and at the other extreme rising to choice according to pattern. A raven and a grey parrot were presented with five small boxes covered with lids bearing two, three, four, five and six spots each respectively—the key being a lid with one of these numbers of spots lying on the ground in front of the boxes. Both birds learned to open only that one of the five lids which had the same number of spots as the key pattern. As a control, everything was changed in a random manner from one experiment to the next. There were fifteen positions of the five boxes and very many different positions of the key pattern; the number of units in the key pattern changed with each experiment and there were five places for the "positive" number of spots on a lid corresponding to that of the key. Moreover there were twenty-four permutations of the four negative numbers. The relative situation of the spots of one group and, with the raven only, the size and form of those spots were also changed with absolute irregularity. In the final series of experiments, for each trial a flat 'Plasticine' cake was broken into pieces of highly irregular and broken outlines, the size of a piece varying from 1 to 50 units of surface area; care was taken to make the general patterns of the positive number on the lid as unlike as possible to that of the key pattern. In an experiment such as this it is believed that any clue foreign to the problem was excluded, and yet the raven solved the problem by choosing the positive lid according to the only item which was not changing through all the experiments, that is, the number of spots equal to that of the particular key pattern presented.

The second problem was to estimate, that is, to remember numbers of incidents following each other and thus to keep in mind numbers presented successively in time, independent of rhythm or any other clue which might be helpful. Here again many different methods were employed. At first birds were trained to eat only "x" grains out of many offered without any help being given from a figure. Another task was to eat only "x" peas which were rolled into a cup, one after another, at intervals ranging from 1–60 seconds. Here again there were no figures at all; the peas were delivered as if by a slot machine, one by one, the bird never seeing more than one pea in the cup. The same applied to opening lids of boxes standing in a long row until "x" baits had been secured; since the baits were arranged in the boxes in twenty or more distributions from one experiment to the next, the number of lids to be opened was constantly changing. Still more remarkable was the fact that birds learned to master up to four problems of this kind at the same time. For example, a jackdaw learned to open black lids until it had secured two baits, green lids up to three, red lids up to four, and white lids until it had secured five baits. Similarly, budgerigars learned to "act upon two" when the experimenter said "dyo dyo dyo" and upon three (take only three grains from the heap) when he uttered the words "treis treis treis . . .". A similar result could be obtained with a bell indicating two and a buzzer indicating three.

Since it would appear that, in this experiment, all external clues were carefully excluded, only an inner token could have been responsible for the birds ceasing action when the number was reached. The bird would appear to have made some inward marking of the units he was acting upon, and sometimes those supposed "inward marks" showed themselves in external behaviour in the form of intention movements.

The simplest explanation offered by Prof. Koehler for this inner marking is that it may be made up of equal marks, as if human beings were to give one nod of the head for one, two for two, and so on; it is suggested that this be called "thinking unnamed numbers". On the contrary, the most prodigal assumption which could be made is that the bird did the marking by unequal or qualitatively different marks in fixed order, as if human beings think 1, 2, 3, 4, 5, or, alternatively, a phrase of five different syllables. That, of course, would be named numbers, or real counting.

Apart from one case, Prof. Koehler's simplest assumption would appear to fit the facts best, there being no sign of "number intelligence" at all and no obviously progressive learning ability as in the case of children. Pigeons and budgerigars were considerably upset by changes in experimental conditions during training for a problem, whereas jackdaws grasped the transposition at once. One bird, after having learnt to open a lid with three spots and not touch a lid with four spots, was presented with three and four mealworms moving on the lids instead of spots. The bird hesitated a long time, but finally went to the three mealworms and left the four alone; instead of opening the lid it ate the mealworms from it without opening it at all.

It would thus appear that a given species of bird shows the same ability of grasping unnamed numbers whether they are presented simultaneously or successively; but the ability differs with the species. Thus, with pigeons it may be five or six according to experimental conditions, with jackdaws it may be six and with ravens and parrots, seven.

Similar tests of the same ability have been carried out with man. In this case the groups of figures were presented tachistoscopically by lantern slides, shown simultaneously and carefully timed so that, while they may be fully seen, the time is too short for counting to take place. It is remarkable that, when this is done with human beings, the limit of achievement is of the same order as that shown by birds. Thus, few persons reach eight and many, like pigeons, get no farther than five. Experiments are still being carried out to test the second ability; but there is no expectation that man may achieve better results than the birds, provided named counting is excluded.

LONG ASHTON RESEARCH STATION FIELD DAY

THE exhibits at the Long Ashton Research Station Field Day on July 10 included several of particular scientific interest. In the Pomology Section, Dr. L. C. Luckwill demonstrated methods used in the biological assay of growth substances and inhibitors, and showed the application of paper chromatography to the separation and identification of growth substances. The test objects used were sections of wheat coleoptiles, unpollinated tomato ovaries, and excised nodes of *Coleus*. The application of these techniques to the study of problems of fruit set and fruit drop in apples was also illustrated. Another exhibit dealt with the use of α-naphthalene acetic acid as a fruit-thinning agent. This substance applied to apple trees within three weeks of petal-fall has been shown to inhibit seed development, thereby leading to an increased drop of developing fruitlets. The method is likely to prove of value for improving fruit size in heavy-cropping varieties and in controlling biennial bearing.

Dr. D. J. D. Nicholas, of the Plant Nutrition Section, had exhibits elucidating the technique of employing *Aspergillus niger* (Mulder's strain) for the determination of metal micronutrients in soils and plant-tissue homogenates. The assay is specific and quantitative for each micronutrient and gives results which are often below the limits of chemical detection. The trace metal requirements of other species of *Aspergillus* and *Penicillium glaucum* were shown to be similar to those of *A. niger*.

Other aspects of the biochemistry of *A. niger* illustrated were sugar utilization, vitamin B_1 and B_{12} production, respiration-rates, amino-acid metabolism and dehydrogenase activity of spores, under various metal deficiencies.

Dr. Nicholas also demonstrated the incidence of iron deficiency in pot-soil culture plants of tomato given nickel, cobalt and zinc, singly and in combination, and in oat given copper only. The metals, including iron, are extracted from fresh leaf tissue with glass-distilled water in micro-mills made of 'Pyrex' glass. Cation exchange resins, for example, 'Zeokarb 215' or 'Amberlites I.R. 100' and '125', are used for concentrating the trace metals and for separating them from the anions. The metal contents of tissue homogenates before and after passage through ion exchange resins are determined as well as the total amounts in dry matter. The appearance of iron chlorosis is paralleled by a decrease in chlorophylls *A* and *B* as determined by a quartz spectrophotometer.

Another exhibit showed the degree of correlation between final yield of crop plants, grown in factorial experiments, and the mineral status determined for various plant portions, at intervals during the season. In this work, a fractionation of the total mineral nutrients is made by maceration techniques and deep-freeze methods. Correlation coefficients between the results of these methods and those of ash analysis were shown.

In the sand culture investigations under the direction of Dr. E. J. Hewitt, the main work demonstrated comprised a factorial study on cauliflower of the relationships of molybdenum supply to source of nitrogen. In this trial it was shown that leaf symptoms of molybdenum deficiency developed strongly with nitrate or ammonium nitrate but were less marked with nitrite or urea. Ammonium sulphate was toxic alone but not in the presence of added molybdenum-free calcium carbonate. Except for a slight ammonium toxicity, growth was good for all sources of nitrogen in the presence of a normal molybdenum supply.

Molybdenum toxicity (500 p.p.m.) was severe with urea or ammonium sulphate or citrate, but was barely evident with nitrite, nitrate or ammonium nitrate.

Ascorbic acid content of the plants was much reduced by molybdenum deficiency, independent of the type of nitrogen supply. These results suggest a role of molybdenum closely related to nitrogen metabolism but not entirely dependent on the source of nitrogen.

A feature of the work at Long Ashton is the extent of collaboration between the various sections. The Insecticides and Fungicides Section, for example, carries out conjoint work with the Sections of Organic Chemistry, Physical Chemistry, Entomology, Mycology and Pomology. Modifications of the structure of DDT were demonstrated in work by Dr. D. Woodcock, Mr. E. J. Skerrett and Miss P. M. James on the relationship between chemical constitution and insecticidal action. Dr. J. T. Martin's exhibit dealt with the extent and permanence of deposits of DDT and rotenone on apple shoots and on soft fruit. He showed also the progress of investigations on the active principles and methods of assay of derris root.

Dr. W. D. E. Thomas and Mr. S. H. Bennett illustrated the application of a radioactive tracer in following the absorption by apple, chrysanthemum, *Coleus* and bean plants of a systemic insecticide (*bis*dimethylaminophosphonous anhydride). The use of the radioanhydride has yielded information on the factors affecting the absorption of the insecticide by leaves, its translocation and its subsequent breakdown. Parallel biological experiments on aphids using the radio-inactive anhydride permit an evaluation of the lethal concentration within the leaves.

Other applications of the use of radioactive tracers were shown in pot culture studies on the phosphate uptake of tomatoes in cobalt-rich soil (Drs. Thomas and Nicholas) and on the effects of clean cultivation compared with grass cover on the phosphate uptake of apple root stocks (Drs. Thomas and C. Bould).

Miss A. Crang and Miss M. Sturdy, of the Domestic Preservation Section, had on view bottled fruit showing the effect of temperature of processing on the enzyme activity of pears and plums. Some varieties of both fruits have an oxidase enzyme system which is still active at temperatures which had been recommended for bottling as sufficient to prevent spoilage by micro-organisms. The result is that the uppermost fruits, in the headspace of the jar, become brown and this discoloration spreads over the rest of the fruit if left partly uncovered for any length of time after opening.

An investigation of the enzyme activity in these fruits shows that it varies considerably in the different varieties and stage of ripeness of the fruit. Higher temperatures or longer times of processing are being worked out to prevent serious discoloration without over-cooking.
R. W. Marsh

MIXING AND AGITATING

Although agitation constitutes one of the basic or unit operations of chemical engineering and finds application, in one form or another, in nearly every major industry, very little is yet known about its mechanism or about the efficiencies to be expected from well-designed industrial stirring equipment.

A conference on "Mixing and Agitating in Liquid Media", arranged by the Institution of Chemical Engineers and held at the Royal Institution on July 17, was opened by Sir Harold Hartley, president of the Institution of Chemical Engineers. Sir Harold emphasized the need for more research and practical data on the hydrodynamics of systems in turbulent motion; and he referred in particular to the factors governing the operation and efficiency of processes such as that of the catalytic hydrogenation of fats, in which the three-phase interface required for rapid reaction has to be produced by agitation.

The introductory paper to the conference was given by Prof. D. M. Newitt, G. C. Shipp and C. R. Black, and reviewed briefly recent theoretical developments relating to the conditions which must be imposed upon heterogeneous systems to give rise to, and maintain, dynamic uniformity. The extent to which existing equipment reproduces the 'ideal' flow pattern for rapid and complete mixing was discussed by B. N. Reavell, who showed how a knowledge of the flow properties and viscosities of suspensions can be made to serve as a basis for classifying the wide variety of mixing problems encountered by the chemical engineer.

The importance of the application of hydraulics and hydrodynamics to the study of mixing was referred to by several speakers. Describing the mixing action of free jets, H. Fossett advocated the use of models to enable the hydraulic criteria governing their action to be established. From a rather different point of view, Prof. F. H. Garner and A. H. P. Skelland illustrated, by a ciné-film, the conditions under which internal circulation can be produced in droplets of a dispersed liquid phase; their experiments lead to the conclusion that the surface viscosity of the fluid in the droplet is probably a major factor in determining the onset of circulation.

The more practical aspects of the subject were dealt with in two papers devoted to the special problems of the fuel and ceramic industries. R. A. A. Taylor, of the Fuel Research Station, described the processes by which coal is suspended in, or incorporated with, water, oil, tar and other liquids, while F. J. Goodson and Dr. A. E. Dodd discussed the manufacture of earthenware bodies by a method in which the ingredients—china clay, ball clay, calcined flint and Cornish stone, disintegrated and dispersed in water—have to be mixed in the correct proportions and as uniformly as possible In both papers the operational and economic factors governing the choice of equipment were stressed.

Among the visitors taking part in the discussion were Mr. Thomas Chilton, president of the American Institute of Chemical Engineers, and Prof. H. A. Kramers, of the University of Delft.

D. M. Newitt

ORIGIN AND IMPROVEMENT OF CULTIVATED PLANTS

A useful review by M. B. Crane of past and present methods used in crop improvement forms the text of the Masters Memorial Lectures of the Royal Horticultural Society for 1950 (*J. Roy. Hort. Soc.*, 75, Parts 11 and 12; November and December 1950). Most of the crops of gardens and farms in Great Britain have attained their present economic desirability either as gene-mutations, through autopolyploidy, or by selection of interspecific hybrids with or without chromosome doubling. The sweet pea, Chinese primula, tomato, raspberry and edible pea are examples of improvement by gene-mutations.

Periclinal chimæras combined with gene-mutations have given certain economically acceptable plants. The potato variety Golden Wonder is a periclinal gene-mutation of the older Langworthy, differing only in its skin. Raspberries, pears, apples, tulips, hyacinths and narcissi are examples of plant improvement by autopolyploidy; chromosome numbers of the 'wild' form have been trebled or quadrupled in the cultivated variant. The strawberry provides an example of interspecific hybridization between the species *Fragaria vesca*, *F. elatior*, *F. virginiana* and *F. chiloensis*. Plums have arisen as interspecific hybrids between *Prunis cerasifera* and *P. spinosa*; but here the hybrid has been subject to polyploidy.

Mr. Crane dealt in his second lecture with the use and extension of these methods in practice. Polyploidy can be induced by treatment with the drug colchicine, by heat shock of plant shoots at 45° C. for one or two hours, by decapitation, and by exposure to X-rays. The action and interaction of genes is now studied very intensively, though the effect is to reveal a complexity far more bewildering than the original Mendelian ratio. This knowledge is put to practical use, however, in such problems as that of raising the vitamin A content of maize. The gene affecting this is related with endosperm colour. Octaploid organization of the dahlia makes possible the fascinating variations of the flower; the expression of dominance is more variable than in diploid plants. Vegetative propagation is a method of perpetuating hybrid vigour, and this fact could be used more consciously by plant improvers. Several examples were given of breeding for resistance to fungal diseases and insect pests. This problem is, however, complicated by the occurrence of strains in the disease-producing fungi, but several examples of valuable degrees of resistance are now known. They contribute significantly to the economy and food of nations.

Measurements of Mass Ratios in Nuclear Emulsions

In an earlier communication in *Nature*[1], we have described a method of measuring photoelectrically the density of tracks in nuclear emulsions. It is analogous to the method of grain counts and can be used with electron-sensitive emulsions where the overlapping of individual grains prevents the use of the latter method. We have compared the residual ranges of particles from regions of their tracks which show the same projected area per unit length, that is, the same average track width. From these comparisons we have calculated the mass ratios. This corresponds to the method used by Lattes, Occhialini and Powell[2] in grain counting.

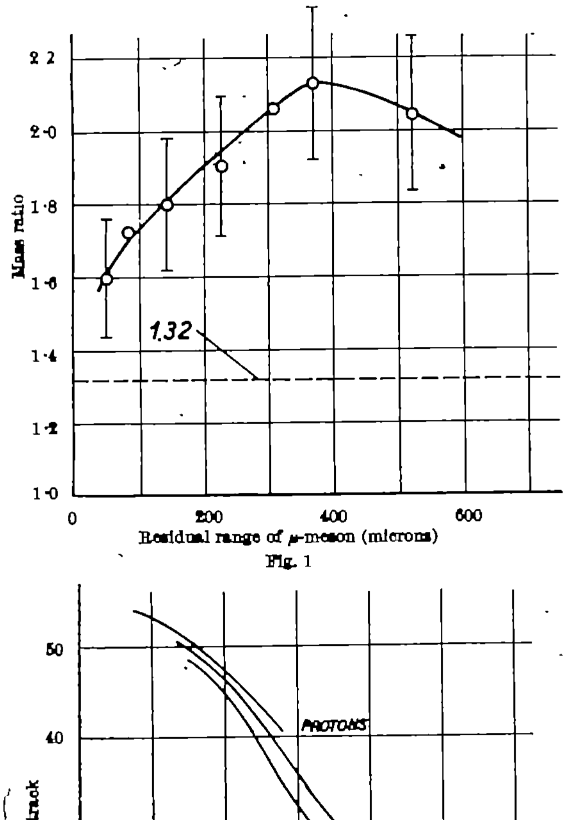

Fig. 1

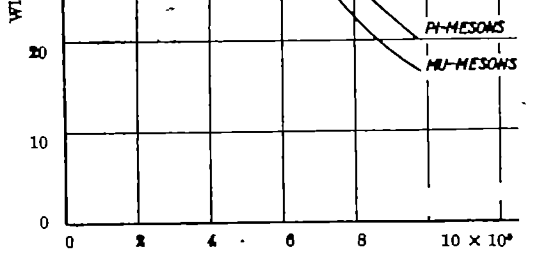

Fig. 2

Fig. 1 shows the ratio between the π- and μ-meson masses obtained in this manner. Fig. 2 shows the velocities corresponding to equal track widths, taking for the masses of protons, π-mesons and μ-mesons the values 1,840, 276 and 212 electron-masses respectively on the assumptions which have been made by Lattes, Occhialini and Powell. Our diagrams show a mass ratio which differs from the value 1·32 given by measurements in Berkeley and varies along the tracks. In this connexion it may be of interest to remember that Lattes *et al.* found the value 1·65 from measurements in nuclear emulsions. The explanation of the anomaly which we have found must be looked for either in an effect connected with the photographic process, or in some effect of the interaction of the particles with matter to which no attention has so far been paid.

A detailed account of the experiments will be given elsewhere (see also the letter by Prof. T. Gustafson which follows).

Density of Tracks of Protons and Mesons in Photographic Emulsions

The experiments by von Friesen and Kristiansson described in the preceding communication indicate that, at the same velocity, π-mesons give a smaller track width than protons, and μ-mesons smaller than π-mesons. The pertinent velocities, $c/5$-$c/3$, lie below those of the Čerenkov effect.

In investigations with photographic emulsions, the assumption is made that the track density, or the probability of making a certain fraction of the grains traversed developable, depends only on the ionization. According to the well-known work of Bohr, Bethe, Bloch, etc., the ionization of electrons by a particle with velocity v, charge e and mass M depends essentially on v and e. The mass M occurs only as a small, and in this connexion unimportant, correction.

We will first discuss the possibility of an explanation connected with the photographic process. According to current photographic theories, the developability of the silver bromide crystals depends on the ionization of the electrons and on certain small lattice defects in the silver bromide. Interstitial silver ions and vacant silver ion lattice sites are supposed to play the most important part in chemically non-sensitized emulsions. The number of such silver ions in a grain is, in our case, supposed to be of the order of 1,000.

It is important that very few silver atoms, perhaps of the order of 10, may be supposed to form the latent image making the grain developable. To form an interstitial silver ion, an energy transfer of about 1 eV. is needed. We have calculated the probability that one of the silver ions in a grain of diameter 0·6 μ gains at least 1 eV. by Coulomb interaction. For a velocity of $c/3$, this probability is only 0·07. For $c/5$ the corresponding figure is 0·19. Even considering the very great sensitiveness of the photographic process, these figures seem to be small. Further, they are in the first approximation independent of mass, so that the difference for protons and mesons is very small. Also other effects, such as the temperature rise in the vicinity of the track, seem to be small and essentially independent of mass. Interactions of the particle with protons in the gelatine are mass-dependent but very small, and it seems difficult to connect them with effects on the grains.

Thus it seems reasonable also to discuss the possibility of specific properties of the mesons, namely, specific interactions between μ-mesons and electrons, and between π-mesons and electrons, which then must be different. In the ionization by electromagnetic forces, distant and near collisions contribute about equally. The assumption of additional short-range interaction has to provide for a reduction of the effect of the near collisions of about 15–20 and 30–40 per cent respectively to be able to account for the experiments. If both positive and negative mesons occur in the experiments, the interaction has to change sign with meson charge. An interaction can exist only for charged mesons.

Further experimental and theoretical work is in progress.

Mechanical Properties of α-Solid Solutions of Copper, with Zinc, Gallium, Germanium and Arsenic

THE strengthening of metals by alloying elements in solid solution is often attributed to the local distortions of the lattice due to the difference in size between the solute atoms and the solvent atoms. In 1942[1], Hume-Rothery and Frye showed that in a series of silver alloys the ultimate Meyer hardness brought about by a given percentage of solute atoms was proportional to the square of the lattice distortion for solutes in the same row of the Periodic Table. In 1950, Dorn, Pietrokowsky and Tietz[2] published the results of tensile tests on a series of aluminium alloys, and showed that the increase in strength was not attributable solely to the lattice strain; but that effects due to the difference in valency between solvent and solute must be taken into account. Thus, they suggest that the hardness of the alloys is given by the equation

$$F = \Delta a + K \Delta v,$$

where F is hardness; Δa is change in lattice constant; Δv is $\frac{\text{atomic per cent solute}}{100} \times$ (valency of solute — valency of solvent); K is constant (approximately 1). In their work the unexpected valency of 2 was assigned to aluminium.

We have examined the tensile properties of copper–zinc, copper–gallium, copper–germanium and copper–arsenic solid solutions. When these alloys are produced by identical methods in the form of soft annealed wires of approximately equal grain-size, the ultimate tensile strength and resistance to plastic deformation appear to be almost entirely governed by the electron–atom ratio of the alloys. Fig. 1 shows, for example, the true stress/strain curves of a copper–zinc alloy with 9·00 per cent by weight of zinc, a copper–gallium alloy with 4·65 per cent of gallium, a copper–germanium alloy with 3·34 per cent of germanium, and a copper–arsenic alloy with 2·48 per cent of arsenic. All these alloys have electron–atom ratios (assuming the usual valencies of the metals) of about 1·087, and their stress/strain curves are as nearly alike as those of four samples of the same wire would be. Fig. 2 shows the 0·5 per cent proof stresses of all the alloys, plotted as a function of electron concentration.

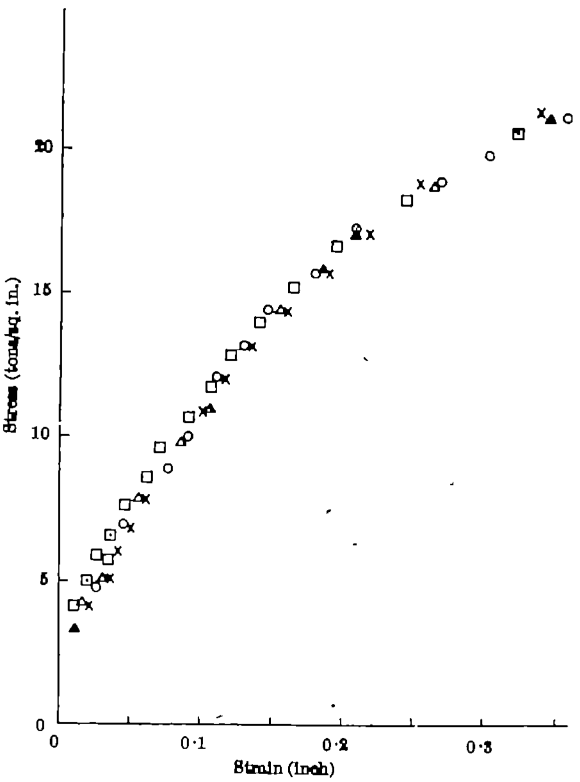

Fig. 1. True stress–strain curves for copper–zinc, copper–gallium, copper–germanium and copper–arsenic alloy wires of approximately the same electron atom ratio

○, 8·78 at. per cent Zn; □, 4·26 at. per cent Ga; ×, 2·95 at. per cent Ge; △, 2·12 at. per cent As. Electron concentration = 1·087 approximately

In this case the alloys behave as if the solute atoms were completely ionized. The increase in the concentration of free electrons in the alloys in Fig. 2 is not more than 18 per cent, and may not account directly for the increased proof stress of the alloys. It seems probable that the high positive charges associated with the solute ions are in some way the

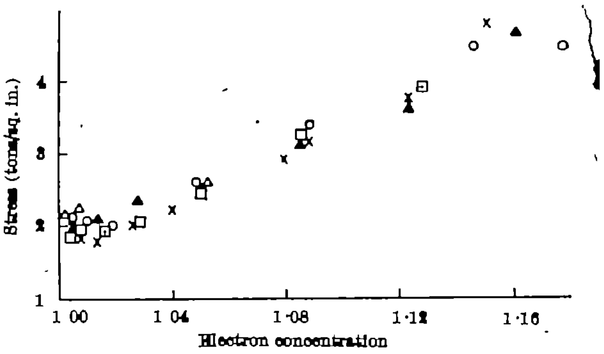

Fig. 2. 0·5 per cent proof stress. ○, copper–zinc; □, copper–gallium, ×, copper–germanium; △, copper–arsenic

cause of the increased resistance to plastic deformation of the solid solutions.

Changes in Lattice Constants of Cr_2O_3 near the Curie Temperature

It has been pointed out[1] that there is a correlation between magnetic and structure transition temperatures for certain antiferromagnetic materials. In the case of Cr_2O_3, with a Curie temperature of approximately 314° K., it was reported that the $4\bar{2}2$ reflexion was resolved into a doublet below the Curie temperature. This communication presents additional information concerning the nature of the structure change responsible for the doublet formation mentioned above.

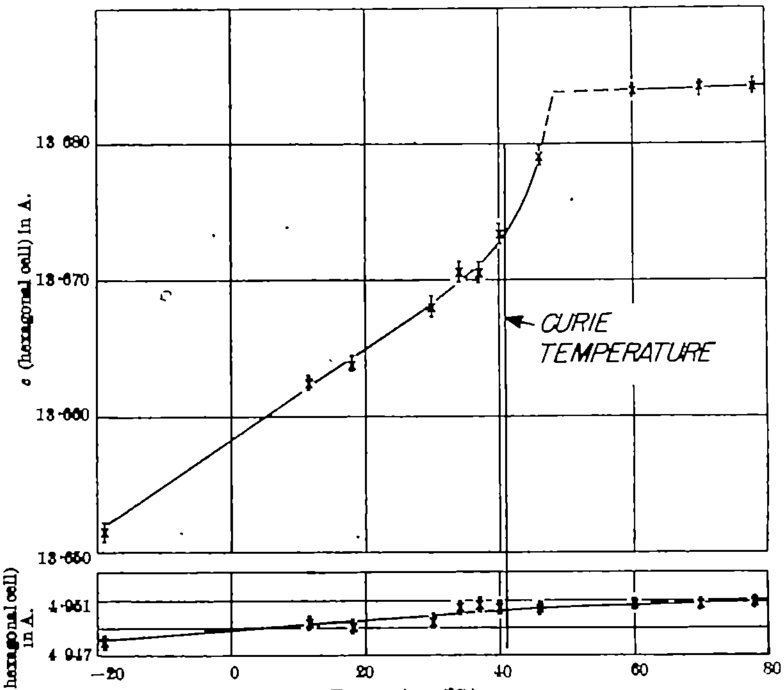
A 10-cm. diameter symmetrical back-reflexion camera was used to provide the high resolution required. An arrangement was made for varying the temperature of the sample from 250° to 360° K. to within ± 1° K. The powdered specimen was mounted on a copper block which had been machined to the proper radius of curvature. For low-temperature measurements, various liquids were circulated through holes in the copper block, which was secured to a 'Bakelite' section to ensure thermal insulation of the photographic film. For high-temperature measurements a heating element was attached to the block. Filtered molybdenum, chromium and copper radiation were used. In the case of copper radiation, a nickel foil (0·001 in.) was placed directly over the photographic film to reduce fogging due to secondary scattering.

Back-reflexion photographs with chromium or molybdenum radiation showed no pattern changes throughout the temperature-range investigated. In the case of copper radiation, the $4\bar{2}2$ and 652 reflexions, which coincide above the Curie temperature, separate into two clearly resolved reflexions as the temperature is lowered. This is the result which was reported as the splitting of the $4\bar{2}2$ reflexion. Calculations for the $\sin^2\theta$ range covered by the camera for molybdenum or chromium radiation show that there should be no superposition of reflexions if a rhombohedral angle of 54° 45′ is assumed for Cr_2O_3. For copper radiation, however, the $4\bar{2}2$ and 652 reflexions coincide. If the rhombohedral angle is appreciably changed, then the condition for superposition of the two reflexions no longer holds. The observations show that above 320° K. the rhombohedral angle is essentially constant and that in a 13°-range below this there is a sharp increase of 2′. An additional increase of 2·5′ occurs as the temperature is reduced to 255° K.

As Cr_2O_3 goes through the transition temperature, the unit cell contracts markedly in the [111] direction, whereas in the direction perpendicular to this the contraction is almost normal.

For ease of calculation the transformation to a hexagonal cell was made. The c- and a-dimensions of the hexagonal unit cell are shown in the accompanying graph as a function of temperature.

The chromium atoms in Cr_2O_3 each has one nearest neighbour at a distance of approximately 2·8 A. Néel[2] has suggested a magnetic structure for Cr_2O_3 in which the atoms in the closely spaced pairs (which lie along the [111] direction) tend to have antiparallel spin alignments. The spin directions of a given pair are also correlated with the spin directions of neighbouring pairs. In such a structure there are ferromagnetic sheets of atoms in the (111) planes with spin directions alternating from plane to plane. An explanation for the correlation between the magnetic structure and the anomalous contraction along the [111] direction has been suggested in a previous paper[3].



The c- and a-dimensions of the transformed hexagonal unit cell of Cr_2O_3 as a function of temperature

There is no indication of a discontinuity in the unit-cell volume as a function of temperature. This is in agreement with the concept that the Curie temperature transition is a second-order phase transition.

Cube-Edges of Uraninites as a Criterion of Age ?

I have suggested that there is a progressive reduction in the size of the unit cell of uraninite-thorianites with time[1]. The ionic radius of Pb^{4+} is appreciably smaller than those of U^{4+} and Th^{4+}. The decay of the parent element causes its substitution by radiogenic lead within the crystal lattice ; because of the differences in sizes of the ions, a shrinkage results. It is therefore likely that this factor can be utilized for indicating the relative ages of uraninites after these have been subjected to an X-ray powder examination. No great accuracy can be envisaged, but such a method would be more accessible to geologists than the highly refined mass-spectrographic one, which can be practised in very few laboratories in the world.

There is a dearth of reliable X-ray data. The recently published values by Arnott[2] are not acceptable, as the systematic errors, inherent particularly in the X-ray determinations of uraninites, were not considered. His results are not correct to the number of significant figures given. I have used the well-known graphical extrapolation method evolved by Bradley and Jay[3], as previously advocated[4]. The only value found in the literature that can be considered accurate is the one recorded by Ingerson[5] for a uraninite from Connecticut. The limits of error are given as ± 0·006 A. in Ingerson's paper ; this is about double the error with which the new determinations were made in this report. Temperature, although observed, has not been considered further, as its effect is thought to be well below the limits of error in this investigation.

In order to assess the reductions of the unit cell, and also to arrive at a correction for the thoria content in uraninites, the cube-edges of specially purified uranium oxide (UO_2) and thorium oxide (ThO_2) were determined, giving respectively 5·470 and 5·599 ± 0·002 A. Assuming Vegard's law for the series UO_2—ThO_2, an approximate correction was applied according to the ratio of uranium oxide to thorium oxide in the uraninites. In order to do this, only material which had been analysed was examined by X-rays, except the Belgian Congo samples, which are known to be nearly free from thoria ; here two samples were tested. The work rests largely on specimens described by Mountain and Holmes[6-8]. The main objective is to measure the effect of the substitution by lead, and the selection of samples is such that other substitutions are of very minor importance.

All the cube-edge values (a_0) in the accompanying table are new observations except the Connecticut one (*op. cit.*). The results show that when allowance for the expansion due to thorium is made, uraninites have a lower cube-edge than pure, lead-free uranium oxide ; this is taken as proof that the lead substitutions take place as postulated above. The first five results (above the line) support the thesis that a progressive reduction in the unit cell does take place with the passing of time. This shrinkage ranges from 0·0025 A. to 0·0041 A. per hundred million years, and such segments of time can be recognized by this method—even with the present limits to accuracy. The narrow variation in the 'shrinkage rate' of four widely differing samples is significant.

Sample	Age (million years)	a_0 determined	a_0 corrected for thoria
UO_2, artificial	0	5·470 A.	5·470 A.
Connecticut (as Ingerson)	280	5·465 A.	5·463 A.
Belgian Congo	600	5·453 A.	5·453 A.
Bisundni (as Holmes)	730	5·448 A.	5·446 A.
Namaqualand (as Mountain)	1,000 ↓ Increase	5·444 A. ↓ decrease	5·429 A.
Gaya (as Holmes)	950	5·481 A.	5·464 A.
Wilberforce (as Holmes)	1,000	5·482 A.	5·460 A.
Namaqualand (as Holmes)	1,000	5·485 A.	5·460 A.

The last three results appear to negative the other results—as a group : among themselves they show the agreement one might expect from the premises set out. The high thoria content common to these samples cannot alone be responsible for their anomalous (?) position, for both groups have a similar, if not identical, Namaqualand sample. The frequently observed loss of thorium D, that is, lead, in thorium-rich minerals may contribute here to give the anomalous (?) high results determined.

The results are considered encouraging, and suggest a method of limited application ; but further study is indicated and is proceeding. A more detailed account is also being prepared for another journal.

It is difficult to refrain from trying to apply the little that seems established so far to local geological problems, for example, the age and origin of the Rand gold deposits. Uraninite concentrates from three different gold mines of the Witwatersrand have yielded cube-edge values ranging from 5·440 to 5·454 A. ; reduction due to a minor thorium content brings these values within the range 5·436–5·449, with an average near 5·442 A. These uraninites are totally different from those from Namaqualand but somewhat comparable to the Bisundni material. The more pronounced shrinkage of the Rand uraninites indicates, however, a greater age which would be about 850 million years. This age would be in harmony with the 'placer origin' of the uraninite, along with the gold, in the pre-Cambrian sediments of the Witwatersrand system.

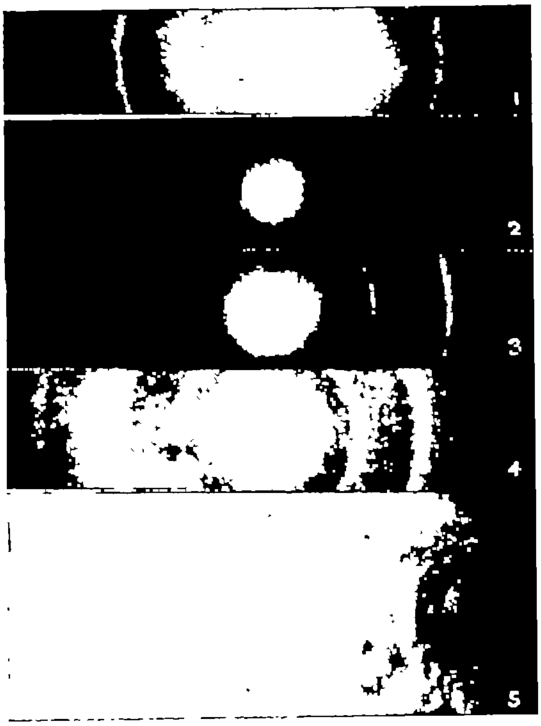
Electron Diffraction by Clay Minerals with a Fibrous or Rod-like Habit

Clay particles deposited from a suspension on to a cellulose film are usually strongly orientated with their basal (001) planes parallel to the film. Electron diffraction patterns obtained with the beam normal to the film reveal only the (*hk*0) diffractions. For most types of clay the corresponding spacings are so alike that such diffraction patterns do not help in identification.

Recently, however, we have found that, of the layer-lattice type clays, halloysite is an exception in this respect. Electron microscopy reveals a rod-like habit of halloysite in contrast to the hexagonal plates of its close chemical analogue, kaolinite. Electron diffraction patterns* of these two clays obtained in transmission with normal beam incidence are also significantly different and not only distinguish clearly between these two but also enable halloysite to be identified with certainty (Figs. 1 and 2). The innermost ring in the halloysite pattern corresponds to the characteristic (001) basal spacing of 7·4 A. This ring is not present in the pattern obtained from kaolinite. Its appearance in the halloysite pattern is due to the effect of the rod-like habit in determining the crystal orientation.



(1) Kaolinite. (2) Halloysite. (3) Attapulgite. (4) *Argilla esmectica verde*. (5) Electron micrograph of *argilla esmectica verde* (×10,000)

Another fibrous clay mineral, attapulgite, which, however, has not a layer-lattice structure, also gives a characteristic normal transmission pattern (Fig. 3) distinct from that of the other clay minerals. The innermost ring corresponds to the (110) spacing of 10·48 A.[1]. Dehydrated montmorillonite and illite have a basal spacing of this order; but this spacing does not appear in their patterns obtained by normal transmission. A Spanish clay, *argilla esmectica verde*, clearly shows this spacing, and its electron diffraction pattern (Fig. 4) as a whole resembles that of attapulgite. Its electron micrograph (Fig. 5) definitely indicates a fibrous habit.

The specimens of halloysite and the Spanish clay were obtained from Dr. D. M. C. MacEwan, of Rothamsted Experimental Station; that of kaolinite from Mr. R. Scott-Russell, of the Department of Agriculture, University of Oxford; and that of attapulgite from Attapulgus, Georgia, through the courtesy of Dr. S. P. Raichaudhuri, of the Indian Agricultural Research Institute, Delhi.

We should like to thank Prof. G. I. Finch for his interest; Mr. H. I. Matthews for the electron micrograph of the Spanish clay; and the Agricultural Research Council, which is supporting the work.

An Interference Spectrometer for the Infra-Red

THE Fabry–Perot interferometer can be used for examining absorption spectra provided that there is no overlapping between successive orders of interference. This means that the range between orders must be equal to, or greater than, the spectral slit-width of the primary monochromator[1]. Suppose that, using a given interferometer, it is possible to resolve a fraction Δm of a fringe order, then under the above condition the resolving power of the combination of interferometer and primary monochromator is more than $1/\Delta m$ times that of the latter alone.

It can be arranged that the diameters of the fringes are very large compared with the height of the monochromator entrance slit on which they are projected, so that the slit embraces only a small fraction of an order. By rotating the interferometer about an axis parallel to the length of the slit, the fringe pattern is passed over the slit, and its structure can be analysed by placing a detector behind the exit slit. In this manner, the Fabry–Perot interferometer may be employed to study *absorption* in spectral regions where photography is not possible. In particular, it can replace the diffraction grating for certain work in the infra-red, leading to a cheaper and more compact spectrometer.

We have constructed an instrument of this kind with glass optics and used it to study absorption spectra under moderately high resolution. For example, the prism monochromator alone just resolves the rotational structure of the harmonic band of HCl at 1·76 μ. When crossed with a Fabry–Perot interferometer having a range between orders of about 16 cm.$^{-1}$, the isotopic fine structure[2] of each rotational band is clearly revealed.

The relatively long wave-lengths of the infra-red region make it possible to use for the interferometer optical flats which are less perfect than those normally required for the visible region. Furthermore, the order of interference is rather low and, as a consequence, the plate separation is small, so that the interferometer is very stable and robust. Antimony seems to be a suitable material for semi-reflecting films, having moderate reflexion and satisfactory transmission coefficients in the range[3] between the visible region and 25 μ. Other possible materials are being examined.

An attempt is being made to link together the motions of the prism and interferometer plates in such a way that the order of interference of the fringe falling on the slit is held constant as the prism is rotated. By this means, it will be possible to record an extended region of the spectrum directly, instead of in steps each of which is equal to the spectral slit-width of the primary monochromator.

Statistical Theory of Solutions

The report of a discussion on this subject[1] prompts me to publish a simple equation which I obtained some time ago for the water vapour pressure isotherm of sulphuric acid solutions. Sulphuric acid is the only liquid that gives heats of mixing with water which are comparable with the heat of wetting of wool, and because the solution is free from mechanical restraint, I set out to determine how far the solution deviated from the regular solution formula[2].

The first step was to determine ω in the equation :

$$\Delta H = \frac{N_A N_B}{N_A + N_B}\,\omega. \tag{1}$$

This can be written :

$$\Delta H = \frac{i/x}{i + 18/x}\,\omega, \tag{2}$$

where i is the number of grams of water per gm. of dry sulphuric acid, and x is the effective 'molecular weight' of sulphuric acid in the solution. Equation (2) is identical with that used by Katz[3] to express his observed heats of mixing. His empirical constants give x as 55—not far removed from one-half the true molecular weight of sulphuric acid—and ω as 16·5 kT.

The second step was to find the vapour pressure relationship from :

$$\frac{p}{p_0} = \frac{N_A}{N_A + N_B}\exp\left\{-16{\cdot}5\left(\frac{N_B}{N_A + N_B}\right)^2\right\} \tag{3}$$

taking the molecular weight of sulphuric acid as 55 and that of water as 18.

On proceeding to evaluate p/p_0, I found that the term

$$\xi = \exp\left\{-16{\cdot}5\left(\frac{N_B}{N_A + N_B}\right)^2\right\} \tag{4}$$

gave the water vapour pressure isotherm for all concentrations, possibly to within the limits of experimental error. The comparison with Wilson's[4] pressure data at 25° C. is given in the accompanying table.

H_2SO_4 (%)	5	10	20	30	40	50	60	70	80
ξ	0·99	0·98	0·91	0·77	0·58	0·37	0·17	0·047	0·005
p/p_0 (obs.)	0·99	0·96	0·89	0·76	0·57	0·37	0·17	0·052	0·008

A superficial interpretation of this coincidence is that two water molecules become attached to each sulphuric acid molecule, which is not unreasonable, and that there is no entropy of mixing. Such a conclusion, if true, should be of general application to solutions with large heats of mixing, but these seem to be few in number. The scanty data available for phosphoric acid show equally good agreement with ω as low as 4·5 kT, but glycerine with 0·73 kT does not obey this relationship.

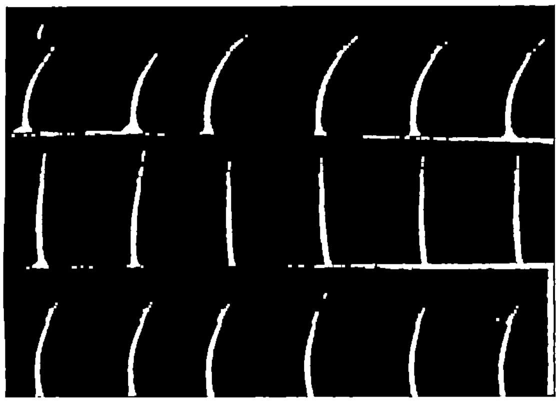
Growth Hormones of Rice Grains Germinated at Different Temperatures

Knowledge of hormone concentration in rice is very meagre. So far as we are aware, systematic attempts have not been made to assay and to ascertain the nature of hormones in rice grains. Avery, Berger and Shalucha[1], in their work on auxin yields from various plant materials, mentioned the auxin content of rice endosperm. Since the publication of their results, improved methods of extraction with greater yield of hormone from plant tissue have been suggested. Hatcher[2] has assayed the hormone content of several grains and studied the relation of its concentration with vernalization response ; but in his list rice grain was not included. The importance of hormone and its relation to vernalization and photoperiodic response has been emphasized by Gregory and Purvis[3], and Cholodny and Cailahjan[4].

It has been suggested previously[5] that the concentration and distribution of the hormone have been the cause of the variation of the flowering duration of tillers and main shoot of rice, var. *Rupsail*. The influence of low temperature is not obligatory for flowering, but its influence on increased vegetative growth as indicated by tillering and height has been noted[6]. The effect of low-temperature stimulation leading to increased vegetative growth and the photoperiodic response emphasizes the need for the knowledge of growth hormones in rice. It would be interesting to find out how far auxin production in rice is related to increased vegetative growth by low-temperature stimulation and to photoperiodic response. In this work the auxin content of rice grains germinated at two different temperatures are noted.

A chamber recently devised by us[7] for the assay of growth hormones in the tropics was used for determining the auxin content of grains of rice and other cereals, and different methods of hormone extraction were compared. An appreciable quantity of hormone has been detected in water extraction. It appears that water extraction alone is effective for the removal of auxin from the endosperm of rice. Higher auxin content by sodium hydroxide extraction is due to slow hydrolysis of auxin precursors as shown by Avery, Berger and Shalucha. In this variety of rice auxin yield is 0·17 million T.D.C. in water and 0·50 million in alkali extraction per gm. of dry endosperm. Avery, Berger and Shalucha noted hormone content to be 0·25 million of T.D.C./gm. in alkali extraction.

The increased auxin content in the present



Avena curvatures for the hormone extract from the endosperm of rice. Top, 0·60 million T.D.C./gm. from dormant endosperm; middle, 0·069 million T.D.C./gm. after 5 days germination at 26° C.; bottom, 0·228 million T.D.C./gm. after 5 days germination at 10° C.

investigation is possibly due to varietal difference and the modification of the extraction method employed.

The assay of the hormone content of rice grains germinated at different temperatures shows that a marked inhibition of the consumption of auxin from the endosperm tissue takes place at 10° C. together with the inhibition of the seedling growth, while at 26° C. a large amount of hormone, about 88 per cent of the total content, disappears from the endosperm within five days (see accompanying illustration). A comparison of the growth of the seedlings shows that during five days the seedlings cultured at 26° C. have two unfolded leaves with 6·2-cm. root and 4·2-cm. shoot length, whereas at 10° C. they have 0·2–0·3-cm. root and shoot length is only noticeable. High auxin content of the seeds germinated at 10° C. was due to the interruption of the hydrolytic reaction yielding auxin from its precursor. Temperature appears to have an effect on the hydrolysis of auxin precursor contained in the endosperm tissue, and the disappearance of hormone from the endosperm has been found to be due to the activity of the growing embryo, as the hormone content is very little changed after the excision of the embryo (see accompanying table).

Exp.	Average degree of *Avena* curvature	Millions of T.D.C./gm. in alkali extraction
Temperature of hydrolysis		
27° C.	27·3	0·60
22° C.	22	0·44
10° C.	16	0·32
5° C.	9	0·18
Endosperm after 48 hr.; 24 hr. with embryo and 24 hr. without embryo	23·6	0·225
Endosperm after 24 hr. with intact embryo	24·2	0·262
Endosperm after 48 hr. with intact embryo	18·7	0·155

In order to ascertain whether the gradual disappearance of hormones from the endosperm was due to the presence of growth inhibitors, the activity ratio of the endosperm extract was assayed by the Skoog's deseeded and Went's standard methods as suggested by Avery, Berger and Shalucha. The ratio found, 3 : 1, is suggestive of the absence of growth inhibitors in the rice endosperm.

We desire to express our sincere thanks to the University of Calcutta for facilities for carrying out this work in the Department of Botany, and to Dr. B. P. Pal, director, Indian Agricultural Research Institute, New Delhi, for his interest and the supply of pure seeds of oat.

Chromosome Elimination in *Saccharum*

IN the sugar-canes there are two cytological features of interest. First, it has been noticed that two types of egg gametes, one with the reduced haploid number of chromosomes and the other with the unreduced diploid number, are formed. From a study of chromosome numbers in certain hybrids (Table 1), it can be seen that in some crosses one or other of these types of gametes, or both, have functioned.

Recent investigations by Bremer[1] have shown that the restoration of the somatic number in the megaspores takes place by a process of endomitosis in the innermost megaspore cell after normal meiosis had taken place. Secondly, it is known that the unreduced gametes of the female parent are capable of developing without fertilization. This is particularly the case in wide crosses such as *POJ* 2725 × *Imperata*[2], and *Co.* 421 × *Coix lachryma-jobi* or *Bambusa arundinacea*[3].

In addition to the two features referred to above, another interesting point was also noticed. The anomalous chromosome numbers of certain seedlings among the hybrids (Table 2) indicated that egg gametes with chromosome numbers different from the haploid or the diploid number had functioned, since the male parents, the meiosis of which was known to be normal, could have contributed only the regular haploid number of chromosomes.

Co. 421, a male-sterile commercial cane, was used as a female parent in a number of crosses and was also selfed under bag. From these, both in wide crosses and in selfs, two types of seedlings were obtained, one type with thick canes having $2n = 118$ chromosomes and the other with thin canes having $2n = 86$ chromosomes. Subramanium[4] has recorded in *Co.* 421, besides normal meiosis, abnormal features in some of the egg mother cells. In these cells the bivalents were found in two groups at the first metaphase, one at the equatorial region with 43 bivalents and the other with 16 bivalents towards the micropylar end. The formation of gametes with 86 chromosomes was inferred to be either from the union of the two nuclei derived from the cell of the dyad with $n = 43$ chromosomes, or by the union of the divided nucleus of the egg cell.

Table 1

Parentage		No. of hybrid seedlings examined	Chromosome number of parents		Chromosome number of hybrids 2n =	Chromosome number of gametes functioning	Nature of female gamete functioning

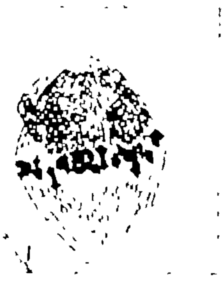
POJ 2725 selfed	2	53	—	96	Parthenogenetic

On a re-examination of the slide in 1947, it was noticed that the two groups of bivalents referred to above were clearly in two different spindles (Fig. 1). Fig. 2 shows the polar view of another cell showing two different metaphase plates in the same cell. It is evident that during the first metaphase two spindles are organized in the same egg mother cell, with the result that two metaphase plates with 43 and 16 bivalents are formed. That only the bigger group with 43 bivalents afterwards takes part in the formation of the egg and therefore in fertilization is inferred from the study of the chromosome numbers of the hybrids (Table 2). Although the fate of the smaller group of chromosomes could not be traced further, it is evident that they do not take part in the formation of gametes and that they are eliminated as a group. The formation of gametes with 86 chromosomes can, therefore, be explained as the result of two processes. First, the elimination of 16 bivalents by the formation of two spindles in metaphase 1, and secondly the cell with 43 chromosomes undergoing endomitosis as seen by Bremer[1]. Instances of chromosome elimination through spindle abnormalities have been recorded before in *Ribes nigrum*[5] and in *Eruca sativa*[6].



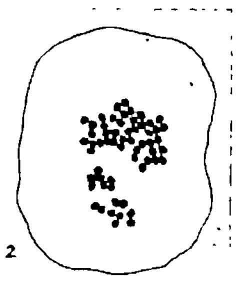


Fig 1. Equatorial view of meiotic metaphase in the egg mother cell of *Co.* 421 showing two groups of chromosomes on two different spindles. In the bigger group all the chromosomes are not shown in the diagram. × 1,400

Fig. 2. Polar view of a similar cell showing two different metaphase plates with 43 and 16 bivalents. × 1,250

Considered from the evolutionary point of view, such chromosome eliminations *en bloc* in polyploids are very significant. They establish the reversible nature of polyploidy. Hitherto, reversal of polyploidy has been known to be due to parthenogenesis. Elimination of chromosomes has been confined to one or two chromosomes only; elimination of chromosomes *en bloc* has been rare. It is possible that this specialized mechanism, which facilitates such chromosomal eliminations, prevails in *Saccharum* because of its high polyploidy. This high polyploidy not only allows the loss of groups of chromosomes, a loss that would be of serious consequence in a diploid, but also provides for evolutionary changes by such special genetic devices; for this reduction releases and exposes to selection new chromosomal races exhibiting a high range of variability. It is also interesting to note that the reduction of chromosome numbers is followed by an increase of the same through endomitosis. Hence, there are two opposing tendencies in operation, yet leading to a genetic balance; for after the elimination, the egg gametes with 43 chromosomes do not function always as such, but undergo a process of endomitosis. This device leads to the fertility of the progeny. The elimination of chromosomes noted in the cane *Co.* 421, therefore, gives us an idea of the evolutionary steps that are in operation in the complex genus *Saccharum*. It also provides an explanation for the existence of different chromosomal races as in the north Indian sugar-canes[7].

The Cement Block, an Improved Block for Spore-formation in Yeast

The gypsum blocks generally used for the production of yeast spores[1] often become infected, on repeated use, with spore-forming bacteria, since they will not tolerate the strong heating necessary for adequate sterilization. We have attempted to prepare a block which can stand such sterilization. After trials with various materials, we finally chose a block cast of Portland cement and kieselguhr, which after hardening in carbon dioxide is sufficiently porous.

The procedure is as follows: 2 parts by weight of kieselguhr and 3 parts of super-rapid Portland cement are mixed carefully; 7–8 parts of water are then added until the mixture is of a plastic consistency. This mixture is poured as a layer about 2 cm. thick into moulds consisting of a cardboard ring placed on a glass plate covered with thin 'Cellophane'. The filled moulds are put in a carbon dioxide atmosphere to harden, for example, in an autoclave. Hardening for three to four days is sufficient, although the blocks appear to be stronger after hardening for a longer period. The blocks are then rinsed in running water for four to eight days until alkali is no longer present.

The blocks can be hardened in air instead of in carbon dioxide. This makes the blocks much stronger; but on account of poor porosity they are not so useful for the present purpose.

The cement blocks may be sterilized by autoclaving at 121° C. for an hour, followed by drying in a hot oven at 80–90° C. for some hours until half-dry. The cooling of the blocks must be carried out slowly as they crack easily on sudden changes in temperature.

The cement blocks are seeded in the same way as gypsum blocks and cleaned by washing under the tap and possibly rinsing for a few hours in running water.

SPORE-FORMATION IN YEAST FOAM AFTER 48 HR. (MEAN OF 6 BLOCKS)

	Vegetative cells	1-spored	2-spored	3-spored	4-spored asci
Cement blocks	44	1	22	25	8 per cent
Gypsum blocks	55	0	19	22	4 ,, ,,

We have used yeast foam (*Saccharomyces cerevisiae*) to test spore-formation on the various blocks which we have investigated. This yeast gives (see table) somewhat better spore-formation on cement blocks than on gypsum blocks; the number of 4-spored asci especially is increased. Other types of yeast which we have tested have also given better spore-formation on cement blocks.

A more detailed account of this work will appear in *Compt. rend. Lab. Carlsberg*, Sér. physiol.

Source of 'Serotonin' in Serum

RAPPORT *et al.*[1] prepared from beef serum a vasoconstrictor substance which was called 'serotonin'. By following the pharmacological activity through various stages from serum itself to the final product, it was considered that the substance finally isolated is, in fact, that responsible for the well-known vasoconstrictor activity of serum. The latter substance, which elsewhere[2] has been called 'thrombocytin', depends on the presence of platelets in plasma at the time of clotting[3,4]. For this reason we have repeated Rapport's procedure, applying it to serum prepared from highly centrifuged plasma, on one hand, and to serum prepared from platelet-rich plasma, on the other.

Blood was collected from cattle at the abattoirs into silicone-coated vessels, using sodium citrate as an anticoagulant. It was spun lightly in a Jouan centrifuge (500 *g* at tip, 340 *g* at surface) to throw down the bulk of the red and some of the white cells; the plasma was removed, pooled and respun in a refrigerated international centrifuge (Conical Head No. 845; 650 *g* at tip). The resultant plasma ('platelet-rich' plasma) was opalescent, and microscopic examination showed that its cellular content was mainly platelets. A portion of this plasma was spun a third time (2,000 *g* at tip) to throw down the platelets and obtain a clear ('platelet-free') plasma. The sediment from the third centrifugation was added to the platelet-rich plasma. By these procedures two plasmas were obtained from the same sample of blood, one clear and cell-free, the other opalescent and rich in platelets. Each was clotted by the addition of calcium chloride, and the sera so obtained (1–2 litres in volume) were extracted in parallel in five stages[1], obtaining as the final product a nitrobarbiturate complex for testing on the isolated carotid artery ring of sheep, dog or ox.

The results were clear-cut. Active preparations were obtained in every case (seven) in which the original serum was made from whole blood or platelet-rich plasma. The average yield from 23 litres of serum was 270 mgm./litre, with losses ranging from 52 to 80 per cent. Isolated arterial rings in 10-ml. baths responded to 50 μgm. or more. (Probably less than 1 per cent of the complex is active substance[1].) On the other hand, serum from 'platelet-free' plasma yielded preparations which were almost devoid of activity, whereas serum from the corresponding 'platelet-rich' plasma yielded preparations sixteen or more times as active. A similar ratio between the activity of such paired preparations was also seen in their stimulating actions on the isolated guinea pig gut or rat uterus, in their ability to liberate adrenaline from the suprarenal gland of the cat, and in their ability when injected into the carotid artery of the cat to cause contraction of the nictitating membrane or miosis.

Serum made by clotting platelet-free plasma to which an equal volume of red cells had been added was inactive.

These results show that the appearance of Rapport's serotonin in serum depends on the presence of the lighter elements of the blood (probably platelets) at the time of clotting. They also suggest that the pharmacological actions of serum, on the test objects referred to above, are due to one and the same substance.

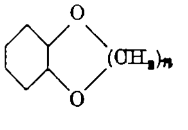
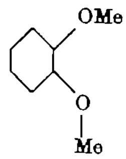
A Novel Connexion between Electrostatic Interaction and Intramolecular Configuration

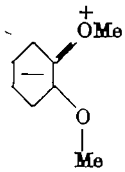
More than a year ago, we reported that the catechol derivatives (I) were being investigated in these laboratories with the object of increasing our knowledge of the relationship between chemical reactivity and intramolecular configuration[1]. At that time we knew that 3 : 7-dioxa-1 : 2-benzo*cyclo*heptene (I, $n = 3$) brominates less readily in glacial acetic acid than do 1 : 3-dioxaindan and 1 : 4-dioxatetralin (I, $n = 1$ and 2 respectively)[2]. This difference in reactivity has also been observed in their rates of hydrogen exchange[3] and is a consequence of the puckered configuration of the seven-membered ring when $n = 3$; the O—CH_2 bonds are oriented out of the plane of the benzene ring and electromeric interaction between this ring and the oxygen atoms is partially inhibited. We expected this interaction to be a maximum in the essentially planar molecules of (I) ($n = 1$ and 2 respectively)[4] and were surprised to find that both these substances are less reactive in the bromination and hydrogen-exchange reactions than is veratrole (II)[3,4].



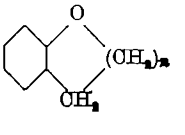
I



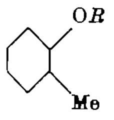
II



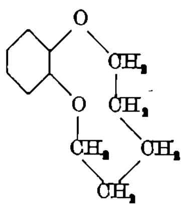
III



IV



V



VI

We assumed that this anomaly was due to direct electrostatic interaction between the two oxygen atoms; we argued that the electric potential of the oxonium ion obtained by electromeric release of electrons from one of the oxygen atoms might be related to the orientation of the neighbouring ether group. The potential should be a minimum when the unshared electrons of this ether group are directed towards the positive charge as in (III), and a maximum when they face in the opposite direction. Thus we considered (II), in which the lower ether group is described as 'facing' the other, to be the configuration which provides ready electrophilic substitution in veratrole, and related the comparatively low reactivities of (I) ($n = 1$ and 2 respectively) to the fact that their ether groups face outwards[5].

We have substantiated this argument in the following two ways: (*a*) Should the anomalously slow bromination of (I) ($n = 1$ and 2) be due to electrostatic interaction between the oxygen atoms, coumaran and chroman (IV, $n = 1$ and 2 respectively) should behave normally. In fact, they are more readily brominated than are the methyl and ethyl ethers of *o*-cresol (V, R = Me and Et respectively), and in this their behaviour is consistent with the enforced planarity of their molecular structures. (*b*) When the heterocyclic ring in (I) includes a sufficiently large number of methylene groups to enable one of the ether groups to face the other, the latter should direct ready electrophilic substitution. We have observed that 3 : 9-dioxa-1 : 2-benzo*cyclo*nonene (VI) is brominated even more readily than veratrole[5]. The pertinent data are assembled in the accompanying table.

Relative Rates of Substitution

	Bromination	Hydrogen exchange		Bromination	Hydrogen exchange
Anisole	1	1	V, R = Me	8	1 5
II	4	3	V, R = Et	16	—
I, $n = 1$	0 2	2	IV, $n = 1$	53	—
I, $n = 2$	0 2	1	IV, $n = 2$	28	—
I, $n = 3$	0·09	0 3			
I, $n = 4$	—	1·5			
I, $n = 5$	16

Crystal Structure of 'Quinaldil'

The substance of empirical formula $C_{20}H_{12}O_2N_2$ prepared by Brown and Hammick[1] by the action of potassium cyanide on quinoline-2-aldehyde, or by the decarboxylation of picolinic or quinaldinic acid in quinoline-2-aldehyde, has been found[2] to be identical with that obtained by Buehler and Harris[3].

A sample of Brown and Hammick's material crystallized from pyridine in forms illustrated in the photomicrograph. They belong to the orthorhombic system, and their characteristic consistent face development with dissimilar terminations shows that they are of the crystal class *mm*.

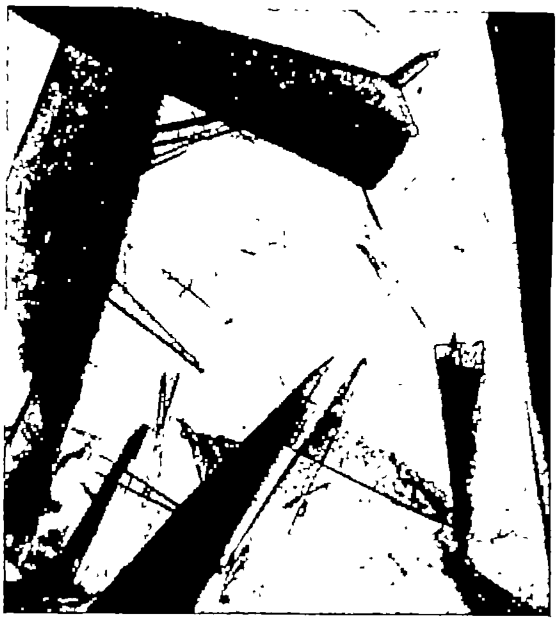

Fig. 1. The crystals in outline resemble a kite or wedge which has its longer axis parallel to the 5 24-A. cell edge, that is, the polar axis *c*. × 30

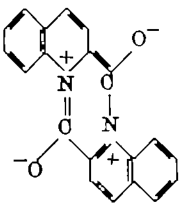
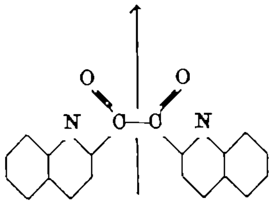
Examination of the crystals by X-ray methods with copper $K\alpha$-radiation gave the unit-cell dimensions $a = 24·8$, $b = 22·5$, $c = 5·24$ A. This cell contains eight molecules. The absent spectra indicate the space group *Fdd*, a result consistent with the crystal class derived from morphology.

In the space group *Fdd* the general point position *xyz* has 16-fold multiplicity, and the eight molecules must therefore lie on 2-fold symmetry axes in the only special position, repeating at 00*z* and its seven equivalents. The molecule, therefore, itself has a 2-fold axis which coincides with a crystal symmetry axis parallel to *c*, along which the repeat distance is only 5·24 A. The suggested planar molecule I, which has the symmetry axis perpendicular to its plane, would therefore have to lie in a plane at right angles to the short *c*-spacing. However, trial shows that flat molecules of this kind cannot be fitted into the available space. Further, a structure consisting of such molecules in parallel array would have strong negative birefringence with the smallest refractive index parallel to the short axis; but the crystals do not behave in this way. The refractive index for vibrations parallel to the length of the wedge is slightly greater than that for vibrations across the wedge. Form I should be planar; but in attempts to overcome these difficulties it was modified by tilting the quinoline parts out of the plane so as to produce a V-shaped molecule. Fourier syntheses based on the atomic positions for such distorted molecules did not develop the structure. Calculated structure factors did not agree with observed, and what partial indication of atomic positions was given arose from the placing of the quinoline ring systems approximately in the positions which they were later found to occupy.



I



II

The form (II), however, leads to the solution of the structure illustrated in the electron density map (Fig. 2). This is an approximation only and is in process of refinement; but it clearly shows all atoms of the molecule separately resolved. The molecule, which is not planar, has a form only roughly indicated by (II). It is non-centrosymmetric and highly polar in the direction of the two-fold axis denoted by the arrow. The arrangement of such molecules, all pointing in the same direction, accounts for the polar character of the crystal, and the fairly steep inclinations of the planes of the aromatic ring systems to (001) are in agreement with the observed optical behaviour.

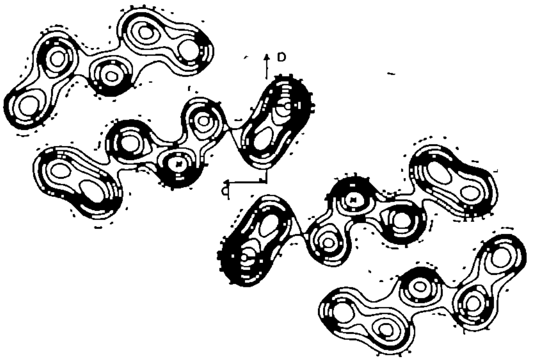


Fig. 2. Electron density map showing molecule projected on a plane perpendicular to the two-fold symmetry axis. Nitrogen (N) and oxygen (Ox) peaks are shown by lettering. All other peaks represent C or CH. The two central carbon atoms are in the plane of projection. Their bonds to the quinoline system slope down from the plane, and those to oxygen are directed above it

Activity of the Chromium–Aluminium Oxide Catalyst System in the Nitrile–Diene and *n*-Heptane Cyclizations

THE chromium–aluminium oxide catalyst system is one most commonly used in the aromatization of paraffinic hydrocarbons. In practice, mixtures containing up to 20 per cent chromium oxide are used, this being regarded as the region of greatest catalytic activity. The work of Eischens and Selwood[1] on this catalyst system established the close relation between the activity, magnetic susceptibility, and state of dispersion of the chromium oxide on the alumina. It was shown that at low chromium oxide content, the chromium oxide aggregates into clusters or islands which build up into two and even three layers in thickness, and which have high magnetic susceptibility and high catalytic activity.

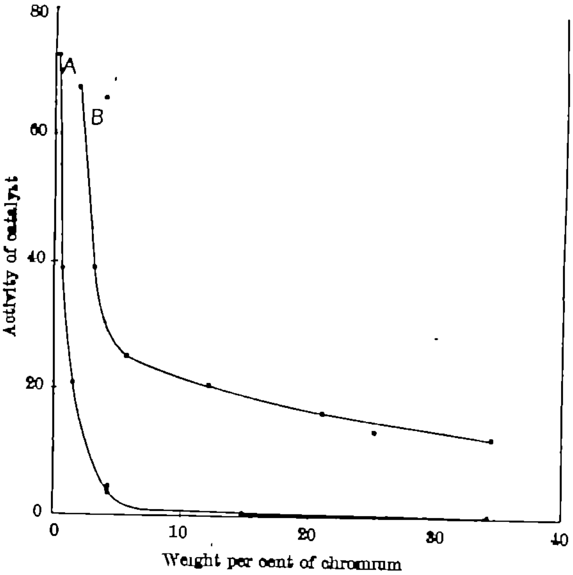
The catalyst activity measurements in these studies were made using the *n*-heptane to toluene reaction, which is an example of a 'one-reactant' cyclization–dehydrogenation reaction. Hawkins and Janz[2] used this catalyst system in their studies of the reaction of simple organic nitriles with 1,3-dienes to form pyridinic compounds. This nitrile–diene cyclization may be considered as an example of a 'two-reactant' cyclization-dehydrogenation reaction. It is of interest to compare the activity–composition relation for this catalyst in the more complex system with that found for the one-reactant case.

Composition and Activity of the Chromium–Aluminium Oxide Catalyst System in (*A*) the Nitrile–Diene Cyclization, and (*B*) the *n*-Heptane Cyclization ·

(*A*) Benzonitrile + Butadiene = 2-Phenylpyridine + H_2.
(*B*) *n*-Heptane = Toluene + $3H_2$.

Catalyst	Activity of catalyst	
Wt. per cent of chromium	Space–time–yield of 2-phenylpyridine (mol. × 10^4/hr./gm. chromium)	Space–time–yield of toluene (mol. 10^4/ hr./gm. chromium)
0 34	72 5	
0·68	39·2	
1·54	20·8	
1 9		67 9
3 2		39 3
4·38	3 45, 4·33, 4 50, 3 96	
5·7		25 4
12 2		20 8
15·4	0·10, 0 07	
21·1		16 5
27·2		13 7
34·2	0 38, 0 10	12·6

A comparison of the activity–composition relation in these two reactions is possible if the results are calculated as activities per unit weight of chromium in the mixed catalysts in each case. For this purpose the results in the nitrile–diene and *n*-heptane reactions have been recalculated in terms of space–time–yield of product per gram chromium. These results are summarized in the accompanying table. A comparison shows that the activities are significantly lower throughout in the nitrile-diene case than in the *n*-heptane case. This is not unexpected in view of the rather different temperatures at which these studies were made (400° C. and 490° C. respectively), and also because of the rather different chemical nature of the reactants in the two systems. It is noticeable, however, that just as in the *n*-heptane case, the activity of the catalyst in the nitrile-diene reaction is high for mixtures containing only small amounts of chromium, and falls rapidly as the amount of chromium increases.



This similarity between the activity–composition relationship emerges more clearly when these data are compared graphically. If the activities of the *n*-heptane cyclization are adjusted by a factor of 10^{-1}, these data can be compared easily with the data for the nitrile–diene reaction (see graph). In the curve for the *n*-heptane case, there is seen a rapidly decreasing activity with increasing percentage chromium in the catalyst, and a noticeable change of slope at about 6 per cent chromium. This 'point' of change of slope and change in activity was shown by Eischens and Selwood to be closely related to similar changes in the magnetic susceptibility of the chromium in this catalyst system. For the nitrile–diene cyclization, the activity–composition relation is strikingly similar. There is the same rapid decrease in the activity with increasing chromium content, and 'point' of change of slope occurs also at approximately 6 per cent chromium. The curve seems to be essentially the same in type as found for the *n*-heptane to toluene reaction.

Hence, the activity–composition relation of the chromium–aluminium oxide catalyst system found in the more complex case of a cyclization–dehydrogenation reaction involving two reactants is quite similar to that observed in the simple case involving only one reactant.

Relationship between Base Saturation and Crop Response to Phosphate in Acid Soils

In an attempt to relate phosphate responses in the field with soil analyses, the most significant correlations I have yet obtained have been between response and the percentage saturation of the base exchange capacity. It should be noted that all the soils, with one exception, lay within the range *p*H 4·7–6·3. In three groups of experiments (fifty-six observations) on wheat, grass and millet, the regressions of crop response (percentage increase in yield due to superphosphate over control) on the percentage saturation of the base exchange capacity were highly significant ($P < 0{\cdot}01$) in spite of the fairly wide variation in soil types. The relationship was an inverse one, and the equations indicated that phosphate responses are not to be expected when base saturation exceeds about 80 per cent. A similar relationship was found between response and exchangeable calcium expressed as a percentage of exchangeable calcium plus exchangeable hydrogen, that is, in units similar to the percentage saturation of the base-exchange capacity.

These results indicate that the percentage saturation of the base exchange capacity (or exchangeable calcium expressed as above) are, in acid soils, a measure of the availability of the soil phosphate. Additional support for this is given by the fact that the control yields were significantly and directly related to the percentage saturation of the base exchange capacity, while the phosphate response was significantly and inversely related to the control yield. On the other hand, the amounts of acid-soluble phosphate (Truog's method and phosphate soluble in 0·1 *N* hydrochloric acid), adsorbed phosphate (extractable with 0·5 *N* neutral ammonium fluoride) and water-soluble phosphate (Burd's method)[1] showed no such conclusive correlations with response or control yield. Typical results, selected from the grass experiments (see Table 1), are illustrative.

A few discrepancies were found between the magnitude of phosphate response and the degree of base saturation, but these could well be referred to adverse field conditions and the different effects of the soils on the efficiency of the added phosphate.

Table 1

Soil No.	p.p.m. P_2O_5.			Per cent sat. base exchange capacity	Per cent resp.	Control yield (tons/acre)
	Ads.	Acid sol.	Water sol			
6708	29	49	4·3	44	50	0 7
6621	18	10	4 1	54	21	1·6
6577	27	5	1 3	60	15	2 7
6025	27	22	5 0	64	12	1·8
6633	16	48	1 2	68	9	1 9
6585	24	8	2 5	74	6	3·1
6645	134	155	9·4	81	−2	3·8

Table 2

Per cent saturation of the base exchange capacity	Average percentage response to phosphate		
	Wheat	Grass	Millet
60 and below	111	26	125
61 to 70	44	11	27
71 and above	21	4	5

On the whole, however, the dependence of response on base saturation was well defined, as shown in Table 2.

There is considerable evidence in the literature that exchangeable bases, notably calcium, can retain appreciable amounts of phosphorus in a readily accessible form for plant use. Allison[2] found evidence of such retention as a $H_2PO_4^- - Ca -$ micelle linkage over the pH range 4·0–6·0, which approximates closely to that for the soils in these experiments. Such phosphate may be considered as saloid-bound, that is, existing as ions in the diffusible ionic atmosphere outside the soil micelle. Saloid-bound phosphate can undergo secondary reactions in the soil to the less available colloid-bound form which is directly associated with the micelle and is non-diffusible.

Such transformations have been reported by Barbier and Chabannes[3], while Ravikovitch[4] has demonstrated that as the degree of base saturation decreases, the proportion of colloid-bound to saloid-bound phosphate increases. A high degree of base saturation in acid soils implies, therefore, that conditions are favourable to the retention of part at least of the soil phosphate, in the available saloid-bound form. With decreasing saturation there is an increasing probability of the soil phosphate existing in the less available colloid-bound form. The percentage saturation of the base exchange capacity is, therefore, directly related to phosphate availability and inversely to phosphate response.

In acid soils a study of base-saturation data offers a logical approach to the problem of relating chemical tests with phosphate response and availability. In conventional methods a number of forms of phosphate of different degrees of availability are usually measured, or secondary reactions may take place during the extraction procedure, making the resultant value in either case difficult to interpret. In contrast, the percentage saturation of the base exchange capacity refers to the conditions governing the existence of a single form of available phosphate. It is more important to know whether available phosphate is likely to be present than the amount of some form arbitrarily, but often incorrectly, assumed to be available. I have not yet attempted to measure the amount of saloid-bound phosphate present because it is doubtful if, in fact, such a procedure is necessary. All the soils so far investigated appear to have an adequate amount of native soil phosphate for satisfactory plant growth, provided only that the degree of base saturation is sufficiently high.

Determination of Sodium Gentisate by Chromatography and Fluorescence

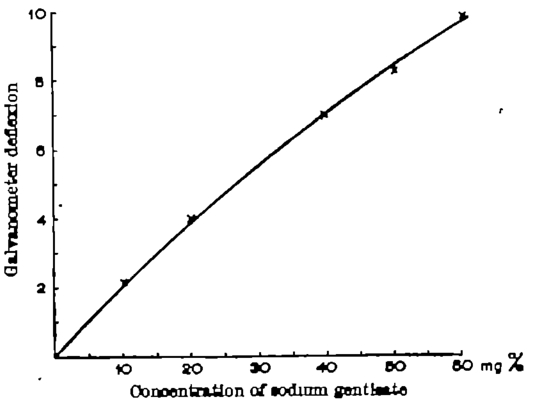
The determination of sodium gentisate (2 – 5 dihydroxybenzoate) in urine is important because of the use of gentisate as a therapeutic in rheumatic fever, and the presence of sodium gentisate in urine after administration of sodium salicylate[1].

We have devised a quantitative method for the determination of gentisate in urine. Portions of 10 c.mm. of the urines are placed on Whatman No. 1 filter paper at a distance of 5 cm. from the edge of the paper; also some spots of known gentisate concentrations are applied. A chromatogram is developed using the ascending technique[2] with the upper layer given by a mixture of two parts of benzene, two parts of glacial acetic acid, one part of water (cf. ref. 3). After 18 hr. at room temperature under an air-tight cover the paper is dried in the air. The gentisic acid is now made visible by its strong blue fluorescence in ultra-violet light, using a Philips *HPW* lamp, which emits the wave-length 3655 A. The R_F value of gentisic acid in these conditions is 0·1–0·2. For quantitative determination it is necessary to be sure that the ultra-violet intensity is the same for each spot.

The fluorescent spots are measured with a selenium cell (diameter 1 cm.). The cell is placed under a piece of lead glass 5 mm. thick (the same glass as used in X-ray screens). Above the cell, which is mounted in a wooden frame, a zinc plate is mounted with a circular diaphragm above the cell and of the same size as the cell. The ultra-violet lamp is mounted in a frame about 17 cm. above the plate and perpendicularly above the diaphragm. The strip of paper with the spots is cut out (perpendicular to the direction of development) and is drawn between the plate and the wooden frame, so that each spot passes under the diaphragm. The lead glass does not transmit the ultra-violet, as is seen by the absence of fluorescence behind the glass.

The largest spot must be smaller than the area of the diaphragm. The deviation of the galvanometer plotted against the concentration of known solutions of pure gentisic acid treated in this way proved to be nearly a straight line (below 60 mgm. per cent) (see graph). This line passes through the origin if the blank given by the paper under the ultra-violet lamp is taken as the zero point. This blank value is due to transmission of a little violet light.

At higher concentrations than about 60 mgm. per cent a photocell of at least 2 cm. diameter should be used, as the (elliptical) areas of the fluorescent spots become otherwise larger than the photocell area.



We believe that with such photocells the linearity should be valid up to higher concentrations; the accuracy is about 1 mgm. per cent.

By dissolving gentisate in normal urines it was found that this method of determination of gentisate is not disturbed by other substances present in urine.

Confusion with substances such as salicylic acid and salicyluric acid is impossible because they move faster in the chromatogram (R_F ± 1·0 and 0·3–0·4). Furthermore, the gentisic acid is characterized by its strong blue fluorescence, and by the fact that standard concentrations of gentisate are always chromatographed on the same paper.

For urine this method is more specific than colour reactions with phenol reagents[4,5], especially when salicylic acid is also present.

The present method is a simplification of a more complicated method, which was used formerly in our Laboratory[1]. With this method it was found by Winkel[1] that up to 30 per cent of a given dose of salicylate is recovered in the urine as the gentisate in rheumatic fever.

The accuracy at low concentrations can be increased by applying more than one quantity of 10 c.mm. to the chromatogram paper.

The method may be useful for determination of other fluorescent substances.

Our thanks are due to Prof. E. Gorter for his interest in the development of this method of determination.

Destruction of Dinitrophenyl Amino-Acids by Tryptophane

The only dinitrophenyl amino-acids revealed by paper chromatography[1] and the use of silica columns[2] during an attempt to identify and estimate the free amino groups of lysozyme by the method of Sanger[3] were ε-dinitrophenyl-lysine and *bis*-dinitrophenyl-lysine. The recovery of the former from hydrolysed dinitrophenyl-lysozyme, using silica columns, suggested that lysozyme contains five non-terminal lysine residues; but the amount of *bis*-dinitrophenyl-lysine recovered was only one-third of that to be expected from one N-terminal amino-group. Similar results were obtained when lysozyme was first treated with urea[4], or when the conditions of reaction with 1 : 2 : 4-fluorodinitrobenzene were varied.

Control experiments showed that whereas *bis*-dinitrophenyl-lysine alone could be recovered almost completely after refluxing with 20 per cent hydrochloric acid for six hours, only 60–76 per cent was recovered when lysozyme was also present. Similar values were obtained when the lysozyme was first hydrolysed for six hours, the *bis*-dinitrophenyl-lysine added and the mixture again refluxed for six hours. The intact protein was therefore not responsible for the destruction of the dinitrophenyl amino-acid. The amounts of lysozyme and dinitrophenyl amino-acid used in these experiments were equivalent to those present during normal hydrolysis of dinitrophenyl-lysozyme.

The original tests of Porter and Sanger[4] for the recovery of dinitrophenyl amino-acids were carried out in the presence of globin. A striking difference between globin and lysozyme is the relatively large amount of tryptophane (10·6 per cent)[5] in the latter protein. It was found that refluxing *bis*-dinitrophenyl-lysine in the presence of tryptophane gave low recoveries of the same order as those obtained in the presence of an equivalent amount of lysozyme. On the other hand, the dinitrophenyl amino-acid could be recovered almost completely (Table 1) after refluxing with other representative amino-acids (alanine, arginine, serine, tyrosine and aspartic acid).

Table 1. Recovery of *bis*-Dinitrophenyl-lysine
(1·28 mgm. dinitrophenyl amino-acid, 6 hours refluxing with 5 ml. 20 per cent hydrochloric acid)

Substance	Amount added (mgm.)	Per cent recovery
—	—	97
Lysozyme	40	68
Tryptophane	4·4	73
Alanine	2·9	96
Arginine hydrochloride	6·85	96
Aspartic acid	8·23	93
Serine	3·23	95
Tyrosine	3·8	94

The amounts of amino-acids were equivalent to 40 mgm. lysozyme except in case of tyrosine

The rate at which *bis*-dinitrophenyl-lysine (1·28 mgm.) is destroyed when refluxed with tryptophane (4·4 mgm.) is shown in Fig. 1 and the effect of increasing the amount of tryptophane in Fig. 2. It will be seen that with sufficient tryptophane the destruction of the dinitrophenyl amino-acid is nearly complete in 24 hr.

Control experiments showed that the loss of *bis*-dinitrophenyl-lysine is not due to adsorption on the humin formed from tryptophane during hydrolysis.

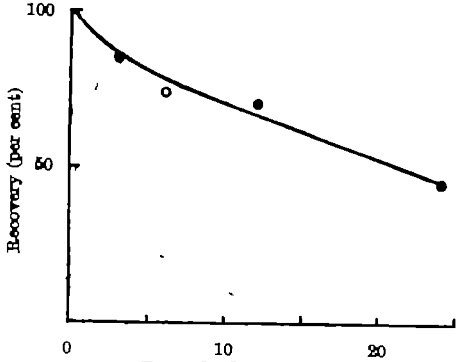

Fig. 1. Rate of destruction of *bis*-dinitrophenyl-lysine

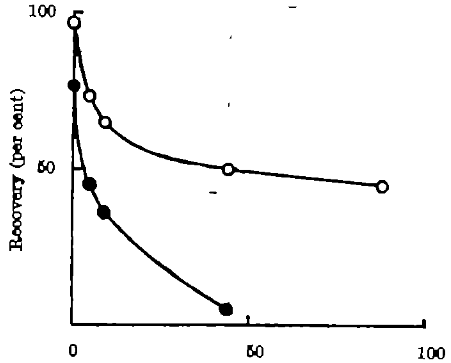

Fig. 2. Effect of added tryptophane on recovery of 1·28 mgm. *bis*-dinitropheny-lysine; ○, refluxing for 6 hr.; ●, refluxing for 24 hr.

It is almost certainly due to chemical reaction between *bis*-dinitrophenyl-lysine and tryptophane (or breakdown products of tryptophane) and, after removal of the unchanged dinitrophenyl amino-acid by ether extraction, a coloured compound can be extracted from the aqueous solution with butanol. On paper chromatograms run with chloroform-ammonia, this product travels almost with the solvent front and cannot, therefore, be another dinitrophenyl amino-acid; it appears to run faster than 2 : 4-dinitro-aniline.

The presence of tryptophane also led to the destruction of certain amounts of other dinitrophenyl amino-acids (Table 2).

Table 2. Recovery of Dinitrophenyl Amino-Acids in the Presence and Absence of Tryptophane

($2 \cdot 67 \times 10^{-6}$ moles of dinitrophenyl amino-acid; 6 hr. refluxing with 5 ml. 20 per cent hydrochloric acid)

Dinitrophenyl amino-acid	Per cent recovery No tryptophane	 4·4 mgm. tryptophane
DNP-alanine	96·5	66
DNP-leucine	100	91
DNP-phenylalanine	99	88·5
DNP-glycine	58	44
DNP-valine	101·5	91

It is clear that quantitative recoveries of dinitrophenyl amino-acids cannot be expected from proteins with a high proportion of tryptophane to the N-terminal amino-acid, especially if a long period of hydrolysis is given. Probably few proteins, however, contain as many as eight residues of tryptophane per polypeptide chain (the number present in lysozyme[5]), so that, in general, the losses would not be so serious as those described above.

Even when allowance was made on the basis of these control experiments for the destruction during hydrolysis of *bis*-dinitrophenyl-lysine, the amount recovered from dinitrophenyl lysozyme corresponded to little more than half the amount expected from one N-terminal lysine residue. This might indicate the inadequacy of these control experiments in assessing the degree of breakdown of the dinitrophenyl amino-acid while in peptide linkage, or the heterogeneity of the protein preparation. Similar results were obtained with crystalline lysozyme prepared by me and that from a commercial source. Electrophoresis of the latter seemed to indicate its purity, though, if the electrophoresis was prolonged, a small second peak appeared.

Fermentation of Malt Extract

AN investigation is being carried out on a sample of malt extract which, after standing for some months, was found to have fermented. As the extract contains about 50 per cent of sugars, mostly maltose, any organism capable of ferment must be highly osmophilic.

Various organisms have been isolated from both fresh and fermented samples of malt extract, but of them only certain yeasts were found capable of fermenting the yeast-free malt when pure cultures were inoculated back into it. With one exception, these yeasts have been found to be species of *Zygosaccharomyces*, a genus which contains many osmophilic species capable of fermenting substances such as maple syrup[1], honey[2], and the intermediate products of sugar manufacture[3].

Five of the isolates were sent to the Centraalbureau voor Schimmelcultures at Baarn, Holland, where all were identified as *Z. japonicus* Saito, though they differed slightly in minor cultural characteristics. *Z. japonicus* was originally found by Saito in "products of fermenting Soya"[1], and has since been recorded by Fabian and Hall in maple syrup and by Fabian and Quinet in honey.

That the organism can grow on substrates of considerably higher osmotic pressure than malt extract is shown by its power of fermenting almost saturated solutions of maltose, and glucose solutions of as high a concentration as 90 per cent w/v.

Studies on the biology of the fermentation are continuing.

My thanks are due to Dr. S. W. F. Underhill for his encouragement, and to the Directors of The British Drug Houses, Ltd., for permission to publish this communication.

Absence of Hydrogen Radiation of Wave-length 21 cm. in the Sun

OBSERVATIONS have been made at the Kootwijk Station of the Dutch Organization for Radio Astronomy, in order to ascertain whether hydrogen radiation of 21 cm. wave-length, detected in the galaxy, would be found also in the sun. The 7·50-metre mirror and the receiver technique were the same as used for the investigations of the Galaxy*. No indication of a spectral line was found. The apparatus was sufficiently sensitive to detect a variation of 1/260 in the continuous radio spectrum.

The line, if present, ought to be an emission line, since the temperature in the corona is decreasing with depth. Collisions would not prevent the emission of the line: for its excitation potential is so very low that half the hydrogen atoms are always on the excited level. Calculation shows that for this wave-length the solar layers are only transparent up to about 9,000 km. above the photosphere; and that in the whole corona and upper chromosphere above this level the number of neutral hydrogen atoms is so small that less than 1/1,000 of the amount necessary for detection is present. The absence of the line is thus entirely understandable.

FORTHCOMING EVENTS

Monday, September 3—Saturday, September 8

British Interplanetary Society (at Caxton Hall, Westminster, London, S.W.1).—Second International Congress on "Astronautics".

Tuesday, September 4—Thursday, September 6

British Institution of Radio Engineers (at Earls Court, London, S.W.5).—Radio Conference, Session 6. "Audio Frequency Engineering".

Sunday, September 9—Friday, September 14

International Union of Leather Chemists' Societies (in the Portland Hall Annexe, Regent Street Polytechnic, Little Titchfield Street, London, W.1).—Second International Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (biophysicist or physicist with experience of radioactive isotopes) in the Department of Surgery—The Secretary, The University, Edinburgh (September 8).

Assistant in Experimental Physics—The Secretary, The University, Aberdeen (September 10).

Assistant Lecturer in Applied Optics, and an Assistant Lecturer in Chemical Engineering—The Registrar, College of Technology, Manchester 1 (September 10).

Assistant Lecturer in Chemical Engineering—The Registrar, The University, Leeds 2 (September 10).

Lecturer, and an Assistant Lecturer, in the Department of Chemistry—The Clerk, Birkbeck College, Breams Buildings, London, E.C.4 (September 10).

Physical Chemist or Biochemist (with a good honours degree or its equivalent in chemistry with either a special interest in physical chemistry or experience in spectroscopy) in the Chemistry Division, Soil Bureau, Wellington, to develop techniques of spectroscopic analysis for a minor element survey of New Zealand soil types—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting A/B.3/64/85 (September 10).

Senior Experimental Officer (with pass degree, or equivalent, in engineering, agriculture or natural science, and with previous experience of work of a similar nature) to take charge of an information unit comprising library, abstracts, publications and a small film and photographic studio—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds (September 10).

Senior Lecturer in Electrical Engineering—The Secretary, South-East London Technical College, Lewisham Way, London, S.E.4 (September 10).

Research Assistant (graduate in geography) in the Department of Geography, to undertake an investigation within the field of Economic Geography on 'The Journey to Work on Merseyside'—The Registrar, The University, Liverpool (September 12).

Assistant Civil Engineer, and an Assistant Mechanical Engineer, in connexion with the design, maintenance and construction of dock and harbour works—The Secretary, Tyne Improvement Commission, Bewick Street, Newcastle-upon-Tyne 1 (September 15).

Chief Examiner in Hygiene—The Registrar, University Office, 46 North Bailey, Durham (September 15).

Curator in Geology—The Director, City Museum, Bristol 8 (September 15).

Lecturer to teach Physics to degree standard, and an Assistant (Grade A) to teach Elementary Physics up to the standard of the General Certificate of Education (Advanced level)—The Clerk to the Governors, Woolwich Polytechnic, Woolwich, London, S.E.18 (September 15).

Chief Coal Survey Officer at the Coal Survey Laboratory in Birmingham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/367 (September 22).

Physicists or Mathematical Physicists, Physicists, Mathematicians or Engineers, at the Royal Aircraft Establishment, Farnborough: (Ref. A.133/51A/BD) Principal Scientific Officer with experience of radar systems analysis and war-time operational research, a strong mathematical bias is desirable, (Ref. A.134/51A/BD) Senior Scientific Officer for theoretical investigations; a knowledge of statistical methods is desirable, (Ref. C.217/51A/BD) Senior Scientific Officer with experience in planning and analysis of flight trials and application of results to project design; a knowledge of servo mechanism theory and practice is required, (Ref. A.135/51A/BD) Senior Scientific Officer with research experience involving arithmetical applications of mathematics in the analysis of physical data and the formulation of problems for solution by automatic computing machinery, (Ref. A.136/51A/BD) Senior Scientific Officer with wide experience of methods of measurement in physics or engineering research, experience and up-to-date knowledge of electronics—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 22).

Specialist Technical Editor (with honours degree in mathematics and/or physics, or in mechanical engineering; experience of teaching, writing or editing of textbooks on such subjects, etc.) at a Ministry of Supply establishment at Chessington—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.242/51A (September 22).

Lecturer in Gas Chemistry—The Registrar, The University, Leeds 2 (September 26).

Chemists and Metallurgists (Experimental Officer grade) at a Ministry of Supply research establishment in Berkshire: Metallurgist (Ref. F.591/51A) with research experience in electrodeposition or in the investigation of the properties of metallic films and coatings, and a Physical Chemist or Physicist (Ref. F.592/51A) with interest and preferably experience in work on ceramic materials—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 29).

Lecturer or Assistant Lecturer in the Department of Zoology, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 29).

Technical Authors at Ministry of Supply establishments at Chessington, Malvern and Farnborough, for the preparation of official instructional publications on the theoretical and practical (including servicing) aspects of airborne and ground centrimetric radar or radio communications equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D 375/51A (September 29).

Engineer (Class 3), and an Assistant Engineer (Class 1), in the Research Section of the New South Wales Department of Road Transport and Tramways—The Agent General for New South Wales, 56 Strand, London, W.C.2 (October 1)

Mechanical Engineer, with headquarters in London, to test and report upon various items of mechanical equipment—The Secretary, Forestry Commission, 25 Savile Row, London, W.1 (October 1).

Principal Scientific Officer (with a first- or second-class honours degree in physics and some knowledge of electro-acoustics and electronics, with experience in the planning of research), R.A.F. Acoustics Laboratory—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4063/51 (October 4).

Scientific Adviser (with a first- or second-class honours degree in mathematics or physics, or mathematics and physics) in the Ordnance Survey Department, Chessington, to advise the Director General on all physical and mathematical matters that arise from the various activities of the Ordnance Survey—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4062/51 (October 4).

Lecturer in Metallurgy in the Department of Mining Engineering, University of Queensland—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 6).

Scientific Assistant (with a university degree in electrical or mechanical engineering or physics) in the Department of Science and Industry—The Director, City Museum and Art Gallery, Birmingham 3 (October 15).

Director (of highest professional and organizational ability, capable of directing physico-chemical and technological research)—The Secretary, Ahmedabad Textile Industry's Research Association, P.O. Box 170, Ahmedabad, India (October 31).

Abstractors for the *Veterinary Bulletin* particularly for literature on chemistry, biochemistry, physiology and pharmacology, in French, German, Italian, Spanish and Scandinavian languages—The Director, Commonwealth Bureau of Animal Health, Veterinary Laboratory, New Haw, Weybridge, Surrey

Adviser in Agriculture (Ref. M.27741/A) and an Adviser in Horticulture (Ref. M.27742/A) for the Iraq Development Board—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting the appropriate Ref. No

Assistant in the Department of Physics and Optics at the College of Technology—The Director of Education, 14 Sir Thomas Street, Liverpool 1.

Assistant (female) with honours degree in physiology (zoology considered) in department chiefly concerned with clinical electroencephalography, also E.M.G., E.C.G., etc., with opportunities for human research—The Secretary, National Hospital, Queen Square, London, W.C.1.

Assistant (Scientific) with practical farming experience and experience of handling machines in the field—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds.

Assistant Lecturer in Physiology—Prof. D. S. Torrens, School of Physic, Trinity College, Dublin.

Assistant Physicist to the Leicester Regional Centre for Radiotherapy at the Leicester Royal Infirmary—The Secretary, No. 1 Hospital Management Committee, 38a East Bond Street, Leicester.

Chemists, Metallurgists and Physicists (Scientific Officer grade) at a Ministry of Supply research establishment near London and the Royal Aircraft Establishment, South Farnborough: Physical Metallurgists (Ref. 582/51A) for the determination of thermal and physical properties of metals and alloys, Physical Chemist or Physicist (Ref. F.583/51A) with an interest in metallurgy or ceramics, for research investigations connected with the preparation of novel ceramic materials, and a Physical Chemist or Physicist (Ref. F.584/51A) for work on surface phenomena and for research investigations into the properties of metallic films and coatings—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Civil Engineers (Main grade) (Ref. H.251/51) and Assistant Civil Engineers (Recruitment grade) (Ref. H.252/51) in the Directorate-General of Works, Air Ministry, in London and the Provinces—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Curator in Anthropology at the Raffles Museum, Singapore—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27456/51 Appts.

Director of the Government of Iraq Chemical Laboratory at Baghdad, and an Assistant to the Director—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.27714.G.

Educational Psychologist for research work in connexion with mental deficiency—The Physician-Superintendent, Royal Eastern Counties' Institution, Abbeygate House, Colchester.

EDUCATION IN THE COLONIES

NOT many years ago those charged with educating the people of the Colonies often came in for considerable criticism. They were frequently told to leave well alone because the Colonial peoples were happy as they were. To-day it is generally realized that Colonial peoples are not happy as they are; they are demanding education, and it should be wisely conceived and generously provided.

Modern conceptions of education in the Colonies usually fall into two main classes, and these have been discussed in an article by W. E. F. Ward (*Universities Review*, 23, No. 3; May 1951). The first conception is political. The Colonies are being educated for self-government within the British Commonwealth of Nations. Self-government is the accepted aim of British Colonial policy; but it is a difficult art, and it would be a mockery to grant political power to people who were not educated to use it. Moreover, a politician, however familiar he may be with Plato, can do little these days without technicians. He needs not only engineers and medical men, but also trained administrators, actuaries, statisticians, and, possibly, public relations officers. To make self-government possible, these men must be trained, and the educational system must be designed to train them. To put self-government as the aim of the educational system takes us a good way in educational thinking and practice.

The second conception of education arises out of the poverty of the Colonies. Their mineral resources are far from being explored; their agriculture could be more productive; their communications are inadequate; they have little manufacturing industry. Their prime need is to develop their natural resources. For this they will need three things: capital, hard work, and knowledge; and two of the three, the hard work and the knowledge, should come from their education, which should be devised to bring rapid economic and social development.

Both these conceptions of Colonial education must be considered in relation to existing circumstances and show that they need to be vigorously pursued. More and more educated Colonial peoples are demanding political responsibility; the remainder must be educated to make self-government possible. More and more natural resources are being devastated through ignorance; the Colonial peoples must be educated both to use and conserve their resources wisely. Colonial educationists are thus fighting not only against human ignorance and wilfulness but also against time.

After paying generous tribute to the work of Christian Churches in Colonial education, Mr. Ward shows that to-day it is men and women of the Colonial Education Service who have most of the responsibility for planning and directing education in the Colonies.

The Colonial Education Service is a unified service: that is to say, its members can pass from one Colony to another, their service being counted as continuous, and their pensions, calculated on a uniform basis, accumulating as the years go by. On the other hand, the Service is far from being unified in the way that the Fighting Services are. It is not appointed and paid from London. Its members are selected by the Secretary of State for the Colonies; but they are appointed by the Governor of the Colony in which they serve, and are paid salaries, fixed by the Colonial Government, from taxes raised in the Colony. It would no doubt be simpler to pay everybody from United Kingdom funds, with suitable local allowances, and to post a man where he is needed. But that would be most unwelcome to Colonial Governments. They like to be masters in their own house: to appoint their own servants, to pay them, and (subject to certain Civil Service safeguards) to control them.

Every British Colonial territory has an educational system, though there are patches in some of them, like the nomadic Somali and Masai tribesmen, where education has not penetrated. Everywhere there is an education department, presided over by a director of education with some sort of educational advisory board. There are primary schools, a few good infant schools (but no nursery schools), secondary schools, teacher training centres and some technical schools or colleges. There are seven Colonial university colleges; but these are not staffed by the Colonial Education Service. Britain does not believe in Government universities.

Except in a few of the smallest territories, there is no compulsory education, for neither the Government nor the Churches can afford to provide schools and teachers for all the children. This is where the Colonies are handicapped by their poverty, by sheer lack of taxable resources. In the big African territories, only a minority of the children can go to school at all. The quality varies. A few of the schools are very good, some are mediocre, many are just bad. There has not been money to provide adequate buildings, especially expensive buildings like science laboratories, workshops and libraries. Consequently, education tends to be much too 'bookish'; this puts severe limitations on the training of local teachers. Nor is there enough money to provide an adequate staff of teachers from overseas.

Yet it would be wrong to imagine that these schools are useless. There is nothing wrong with them that could not be put right by a grant of £50,000 for buildings and equipment, and an annual grant for additional staff salaries. The trouble is that the local Governments have not got the money. They prefer to have one or two really good schools, which can serve as models for the others to copy, and can be used as training centres for teachers from elsewhere. These schools are often very good indeed, as regards staffing, building and equipment.

All this means that the man in the Colonial Education Service, whether teacher or administrator, is kept on the alert. He is always making bricks with the minimum of straw. He has to turn his hand to anything, to improvise. His work is exhausting; but immensely stimulating and worth while.

Teaching and administration are the two main functions of the Service. People often pass from teaching to administration, and sometimes back from administration to teaching. In most territories, the primary school teachers are all locally born. In the infant schools there are still some head teachers with a Froebel or similar qualification who are recruited in Great Britain and are members of the Colonial Education Service. In the secondary schools, and still more in the teacher training centres, there are in the aggregate large numbers of graduate teachers, and it is the normal practice for all newly appointed members of the Service to be posted first to classroom teaching.

The bush education officer has no exact counterpart in Britain. He may be responsible for the general educational efficiency of a district which may be as big as Scotland or as small as Rutland. There may be in his district a Government or Church secondary school with one or two Europeans on its staff, or even properly qualified locally born teachers. There will certainly be other professional colleagues—a district commissioner, an agricultural officer, and a medical man. He may be able to persuade them to help him now and again in some special project, such as a holiday refresher course for the primary school teachers. His work will be a never-ending round of visiting schools, inspecting the state of equipment, listening to the teaching, advising and helping the teachers and often giving a demonstration lesson himself, assessing the schools' eligibility for grant and checking the finances, planning extensions to buildings and planning new schools and collecting the teachers for holiday courses.

The bush education officer is in some ways the key man in the educational system. It is very largely a matter of his personality whether the schools in his area are active or stagnant. This is mainly due to the inadequate education and professional training which most of the staff have received. Many of them have excellent capacities; but too often they have had so little opportunity that they have been able to do nothing but acquire knowledge and a few stereotyped ideas on method and technique. The education officer has to draw out of them what he feels they have in them.

He is like the local education authority's representative in that he is the superior officer of the Government teachers, and has scarcely less power over the teachers in the assisted or unassisted Church or native authority schools. He is in close touch with the mission or other employing body; he can recommend that the school's grant be increased or diminished, that an unassisted school be placed on the assisted list or told to wait. In dealing with missionaries or local government bodies, he is like British school inspectors in being able to give them advice on the condition of their schools. If they need to spend money he cannot compel them to do so; like the divisional executive in Britain, he has to persuade them. The man who can keep his teachers up to scratch, keep on good terms with his Government colleagues in half a dozen different departments and with the representatives of half a dozen assorted missionary societies, persuade a group of canny village elders that if they want a school they must build it themselves, lay his plans for educational expansion and get them accepted by his departmental chiefs and the advisory board at headquarters, could fill most positions in the educational world adequately enough.

The curriculum in schools and colleges is often determined by two considerations: the first, that the pupils have to be prepared for all the multifarious techniques that a modern civilized State requires; the second, that education must be rooted in the pupil's ancestral culture. To some extent these two considerations come into conflict. The dominant European culture has such an attraction for the pupils that they tend to resent anything which diverts their attention from the full-time occupation of studying it. It is not that in general they are hostile to their own culture, though such hostility is a phase which some of them pass through; but most of them would gladly be learned in the lore of their own people if they could become so without giving up the new learning which comes to them from the West.

Hence the greater part of the curriculum reads like a copy of the curriculum in Great Britain—as, in fact, it is. Here and there it is possible to make minor local modifications. Local history and geography play a part in the courses, and are offered in the Cambridge examinations. There was a time when English earthworms and dandelions were sent out on ice to be dissected by African candidates in biology examinations; but they have long since been replaced by local types. Work in art, music and housecraft is often based on local conditions and local culture. But it is not possible to make much variation in an educational system which has to train engineers, medical men, lawyers, accountants, professional men and technicians of all kinds. Students in the Colonies naturally demand professional qualifications that are recognized in Great Britain. The place for local culture seems to be rather in the study of the local languages and literatures, and in school organization and out-of-class activity, than in the study of subjects which are designed to lead to the acquisition of distinctively Western skills. There is no doubt that indigenous culture will have to play a larger part in Colonial education in the future than it does now. One of the great services which the new Colonial universities will be able to render is in undertaking the necessary study of indigenous cultures and in building up a new civilization based on a blend of the indigenous culture with that of the West.

The lack of cultural background is felt over a much wider field than the study of the arts. Except in a few special cases such as the Caribbean, Western education tends to draw the children away from their own social background. Many of them come from illiterate homes, and their parents aspire to see them appointed to a well-paid Government post, preferably one which does not involve hard physical work. The first effect of schooling is thus often to take a child right out of touch with the primitive life in which his parents still live. As a result many critics say that in a territory where agriculture must for many years remain the principal industry and source of revenue, people ought to realize that they are needed on the land; and there must be something wrong with an educational system which enables—or even encourages—people to leave the land and flock to the towns.

The critics, of course, are crediting the school-teacher with a good deal more influence than he has, and they are ignoring a good deal of human nature. To get boys into the mines in Britain one thinks in terms of wages, holidays with pay, housing, pit-head baths and canteens. It will have to be the same in the Colonies. Young people will never be kept on the land by setting school-teachers to preach at them about the importance of agriculture.

Nevertheless, the educationist must do what he can to avoid this unhappy cleavage between educated young people and their rural background. There is little that he can do in modifying his curriculum; but he can set up various adult-education movements and various types of youth work to enable ignorant parents to comprehend the purpose of school education and to enlighten those who remain behind in the villages. This side of education is still in its infancy.

Enough mass education work has already been done, however, to show the possibilities that are waiting to be realized if men and women can be found to undertake it. Tribesmen in Nigeria have built themselves roads and bridges and all sorts of public buildings, from market halls and co-operative shops to maternity clinics. The demand for reading-matter in six different languages among recent illiterate workers in the Rhodesian copper belt kept the printing presses on the strain. In the Caribbean and in East Africa people have begun by realizing with a shock that the school could teach them something even on their own subject of farming, and they have gone on to profit by this discovery in improving their nutrition, their health, their home life, and their general community spirit. Mass education has great possibilities, and might, in fact, go a long way towards healing the rift between formal education and real life. But there is nothing like enough of it yet.

Mr. Ward also shows that educational research in the tropics is an almost untouched field. Visual aids, intelligence tests, English as a foreign language, curriculum and organization, relationship between school and home are only a few of the outstanding topics on which many people have views based on experience, but on which scarcely anyone has yet done any proper research. There is great need of research workers, and this, too, is a field in which it is hoped that the new Colonial university colleges with their institutes of education will be able to help.

THE ESSENTIAL OILS INDUSTRY

The Essential Oils

By Dr. Ernest Guenther. Vol. 4: Individual Essential Oils of the Plant Families Gramineæ, Lauraceæ, Burseraceæ, Myrtaceæ, Umbelliferæ and Geraniaceæ. Pp. xiv+752. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1950.) 90*s*. net.

THIS volume follows the same plan, and achieves the same excellence, as its predecessor (see *Nature*, 166, 753; 1950). The oils here dealt with, however, being predominantly products of the eastern hemisphere, and indeed of the Far East, illustrate in a much more striking fashion the contrast between highly modernized and wholly primitive methods of production, which is so marked a feature of the essential oils industry as a whole.

Palmarosa, cassia and lemongrass provide examples of oils in which the organization and technique of production can have altered little since the era of bulging galleons and buccaneering raids, so pleasantly touched into the background of Dr. Guenther's account of cinnamon and clove. Such oils, obtained from herbs or small shrubs, are highly seasonal in output, and produced in scattered locations, defined partly by ecological suitability for the oil-bearing crop, and partly by unsuitability for any more immediately profitable husbandry. These factors, added to the bulky nature of the crop, and the low weight-proportion of the oil, which is the only valuable part of it, preclude the steady flow and concentration of raw material which alone could offset the capital expense of a modern processing plant. So far as such oils are concerned, therefore, production of essential oils remains a peasant industry, based on the most unambitious standards of living and the crudest distillation equipment, and liable to great unevenness or total interruption of output when political unsettlements compel the peasant's attention more exclusively to his immediate needs of livelihood. The connexion is clearly illustrated by the decline of the Algerian geranium oil industry, linked with the progress of Algiers from colonial status to that of a department of France. In Réunion, under social conditions which Dr. Guenther judiciously describes as "feudal", production of geranium oil maintains its economic equilibrium.

In contrast are the developed industries based on camphor and eucalyptus, each so completely a subject in itself that even such a coinage as "eucalyptologist" must be accepted as a necessary evil; and Dr. Guenther has been wise and fortunate in leaving the appropriate monographs in the hands of specialists, co-ordinated by Dr. T. Hiraizumi, of the Takasago Chemical Industry Co. of Tokyo, and Messrs. A. R. Penfold and F. R. Morrison, of the Museum of Technology and Applied Science, Sydney. The camphor industry, it is true, can show a lineage comparable with that of cinnamon itself; to the Formosan woodcutter, the largest camphor tree in the forest is still a shrine, and each lesser tree a spirit, not to be insulted without offerings of propitiation; but between the forest and the market, Japanese activity, in response to the challenge of artificial camphor, has interposed an organization of singular completeness. The status of the tree as a vegetational dominant over large areas permits of a more systematic harvesting and replacement, and a more thorough study of botanical variations, than is possible with grasses and herbs. To this has been added the utmost possible utilization of all constituents of the crude produce, export or consumption of which without fractionation was prohibited by the Japanese Monopoly Bureau. The number and variety of 'cuts' and isolates from camphor oil may indeed become confusing, and Dr. Hiraizumi's clarification of the subject is accordingly welcome.

Except in respect of its antiquity, the eucalyptus industry stands on a similar footing. Potentially it is capable of even wider expansion, since the very numerous species of the genus show a greater variety among themselves than is often found between oils from different genera or even different families. As examples may be quoted *E. polybractea*, yielding medicinal oil with up to 90 per cent of cineole; *E. numerosa*, with up to 80 per cent of phellandrene, used industrially in ore flotation; and the perfumery oils of *E. macarthuri* and *citriodora*, containing respectively up to 70 per cent of geranyl acetate and 80 per cent of citronellal. Even morphologically indistinguishable trees growing within a few feet of one another may yield wholly different (cineole-rich or piperitone-rich) types of oil. Confusion may be increased by commercial practice in giving a blended oil the name of a single species if it is of the type traditionally associated with that species; for example, *E. globulus*, even though it is well recognized that unmixed oil of that species is not, in fact, marketed from Australian sources. Penfold and Morrison's painstaking comparative review of some two hundred and fifty specific names in the genus is therefore not the least valuable part of their contribution.

The future of the primitive types of essential oils industry is obviously somewhat problematical. A fuller utilization of the raw material would seem to be the first condition of survival. Uses can be found even for the spent material, as, for example, the production of paper in Guatemala from lemongrass leaves after distillation. Improved distillation technique may multiply the number of products, as with the fractions of camphor oil, or improve the yield of specially valuable constituents such as the citral which, through the intermediate stage of β-ionone, hitches the wagon of lemongrass oil to the commercial star of synthetic vitamin A. It may be that in some cases such a degree of development implies no less than the bodily transplantation of the old industries to distant sites where they will constitute staple instead of spasmodic occupations, and where lay-out and transport are specifically adapted to their purposes; and Volume 3 of this work affords evidence that such a solution is physically possible. Dr. Guenther's book will then seem out of date; but scarcely, one may suppose, before then.

E. G. Kellett

FRESHWATER PHYTOPLANKTON

Die Binnengewässer

Band 16: Das Phytoplankton des Susswassers; Systematik und Biologie. Von Dr. G. Huber-Pestalozzi. Teil 3. Cryptophyceen, Chloromonadinen, Peridineen. Pp. ix+310+69 plates. (Stuttgart: E. Schweizerbart'sche Verlagsbuchhandlung, 1951.) 67 D. marks.

THE great importance of freshwater phytoplankton in limnological studies has long rendered desirable a taxonomic treatment of the organisms involved. Such a phytoplankton flora was indeed planned by those responsible for the publication of the valuable "Susswasserflora Deutschlands, Oesterreichs, etc.", although it never reached completion. Huber-Pestalozzi's work, forming part of the series of Thienemann's "Binnengewässer", thus fulfils a useful purpose in supplying this long-felt need. The parts already published (Teil 1, 1938; Teil 2 in two separate portions, in 1941 and 1942), which, apart from containing a general introduction, have dealt with the Myxophyceæ, Bacteria, Fungi, Chrysophyceæ, colourless Flagellata, Xanthophyceæ and Diatoms, have not been available for review. The entire work to date costs about 260 D. marks (upwards of £20) unbound, and three further parts are planned. It will be clear that the cost is almost prohibitive for the private individual, and it may be questioned whether a treatment on a less ambitious scale would not have been more valuable. The need is for a work of a less-expensive character that could be published at a price which would render it accessible to more than libraries and institutions.

The particular part under review deals in the first place with the Cryptophyceæ and Chloromonadineæ, of which no detailed systematic treatment has appeared since that of Pascher in the "Süsswasserflora" (1913). Scherffel's problematical genera *Monomastix* and *Pleuromastix*, the affinities of which are hard to assess, are grouped as a sub-class Monomastigineæ, the remaining Cryptophyceæ forming the sub-class Cryptomonadineæ. The latter are urgently in need of a critical revision, as Pringsheim (1944) has pointed out, and the material brought together by Huber-Pestalozzi will afford a basis for future work on the group. The author provides a useful key to the thirty-two described species of *Cryptomonas*. In the treatment of the Chloromonadineæ no reference is made to recent French work (Chadefaud 1937, Hovasse 1945), especially that relating to *Gonyostomum*, from which better figures than that of Stein of *G. semen* could have been obtained. The author appends to the account of the Chloromonadineæ a discussion on trichocysts which both French authors have studied in some detail. The greater part of the volume is concerned with the important planktonic group Peridinieæ, of which Schiller has comparatively recently (1931) given a detailed systematic account in Rabenhorst's "Kryptogamenflora". The restriction to freshwater species and the provision of detailed keys for such large genera as *Gymnodinium*, *Glenodinium*, and *Peridinium* will make Huber-Pestalozzi's treatment useful to workers on freshwater plankton.

The majority of the 350 illustrations are reproductions and, especially among Cryptophyceæ and Chloromonadineæ, the absence of fresh figures is disappointing. The bulk of the figures are grouped as plates on stiff paper, which must have added to the cost of the work, although most of them could equally well have been reproduced in the text.

F. E. Fritsch

TECHNOLOGY OF ALUMINA PRODUCTION

Tonerde und Aluminium

Ergebnisse und Erfahrungen aus der Betriebspraxis, 1920–1950. Von Dr. Wilhelm Fulda und Dr. Hans Ginsberg. Teil 1: Die Tonerde. Pp. viii+226. (Berlin: Walter de Gruyter und Co., 1951.) 26 D. marks.

THE publisher's notice of this authoritative work states that it is intended to provide what has as yet been lacking—a comprehensive account of the actual working practices of the alumina and aluminium industries. The present volume, on alumina production, certainly fulfils this intention.

While omitting mention of many processes now only of historic interest, it contains much more quantitative information on current operations than did Edwards, Frary and Jeffries's standard work, published in 1930.

After reviewing in detail the properties of European bauxites and to a less extent those of other countries, the book devotes nearly eighty pages to the development in Germany, during a period in which German aluminium production was expanded from about 14,000 tons (in 1920) to 260,000 tons (in 1943), of the classical Bayer process for extracting alumina from bauxite with caustic lye, and its modification the so-called 'tower process'. There follow some fifty pages describing the alternative 'sinter-alumina' process in which the bauxite is heated with sodium carbonate in a rotary furnace; methods of extraction, due to Pedersen and others, in which lime is the extracting agent and still higher temperatures have to be used; and such processes as that due to Haglund, which have as their object the removal of impurities from the bauxite rather than the direct extraction of the alumina itself. The remainder of the book is devoted to processes for extracting alumina from clays and other aluminosilicates.

The book is systematic, essentially practical from the point of view of the chemical engineer, and engagingly clear. It is well provided with flow diagrams and other illustrations. It has behind it the authority of two authors well known in the industry. Dr. W. Fulda died in September 1950; and while the surviving author acknowledges the collaboration of colleagues in the Vereinigte Aluminium-Werke A.G., the book achieves a noteworthy unity of presentation.

All who are concerned with the technology of the primary aluminium industry will welcome this book and will look forward keenly to the appearance of the succeeding volume, which is to deal with the production of the metal.

PRODUCTION OF GLASSHOUSE CROPS

Science and the Glasshouse

By William J. C. Lawrence. Second edition, revised. Pp. xiv+176+4 plates. (Edinburgh and London: Oliver and Boyd, Ltd., 1950.) 15*s*. net.

THIS book is divided into three parts: (1) the John Innes composts, (2) methods of cultivation, and (3) natural illumination in glasshouses, and gives an account of work done at the John Innes Institution on these subjects. Indeed, it is a progress report on experimental work carried out by Mr. Lawrence and his colleagues.

So far as Part 1 is concerned, little need be said; the John Innes composts for seedlings and growing plants are now widely used by growers, and there is no doubt that considerable improvement in plant production has thereby been brought about.

Part 2 deals with several fundamental aspects of plant production, for example, size of pot, firm or loose soil, watering, soil temperature for potting, type of benching in the glasshouse, etc. These are all factors in which tradition has decided the correct way, and tradition dies hard. Moreover, it is probable that tradition will govern many of these factors for some years to come, for to many growers of the 'old school' these new ideas are not welcome. Apart from this diehard attitude, there are several considerations which must be taken into account by the commercial grower. For example, the size of pot into which a plant is potted is very often governed by the space available; this is particularly true in the case of the grower of decorative plants for sale in pots.

The skill of the worker under whose care the plants are placed is a most important factor which cannot be assessed experimentally, but which has a profound influence on the ultimate result. It has frequently been said that the horticultural worker who cannot use the watering can or hosepipe efficiently and intelligently cannot grow a good plant or produce a good crop. There are many similar variable factors in plant production which cannot be standardized except by the most elaborate equipment, but which are controlled to some extent by the human factor. Therefore, however far the fundamental processes of horticulture are standardized the human factor will ultimately decide the quality of the plant.

Mr. Lawrence has, in the experiments described, blasted tradition; he has opened up new lines of approach to many problems; but it is very necessary that the experimental results shall be linked with the economics of plant production, and further experiments on these lines are necessary.

In the last part of his book Mr. Lawrence has explored new ground and has collected together a vast amount of data on the natural illumination of glasshouses. The information given is of great value and has already influenced the design of glasshouses. The importance of light in the production of winter crops is emphasized and suggestions are made for obtaining improved winter illumination. It is difficult to understand why work has not been done previously on this and many other problems concerning glasshouse construction.

This is a book which is stimulating and, in many ways, provoking. It should be read by all who are interested in the production of glasshouse crops, for in it they will find considerable food for thought.

Mr. Lawrence is to be congratulated on the production of this book, which is a contribution to the fundamental knowledge of glasshouse crop production of very real value. WILFRED CORBETT

TECHNOLOGICAL RESEARCH IN SWITZERLAND

Industrial Research in Switzerland

Its Institutional and Economic Background. By Prof. Ronald S. Edwards, in collaboration with Charles La Roche. Pp. ix+111. (London: Sir Isaac Pitman and Sons, Ltd., 1950.) 21*s*. net.

PROF. R. S. EDWARDS has followed his earlier study of the economic aspects of the research associations in Great Britain with a study, in collaboration with Dr. C. La Roche, of the Federal Institute of Technology, Zurich, of the organization of industrial research and development in Switzerland. The book is based on a survey of Swiss industrial research institutions, together with discussions with firms, research institutions, universities and government departments, and includes some information not elsewhere available. There is a select bibliography, prepared by Dr. C. La Roche, and much useful information is collected in the appendixes, dealing with research foundations, the scientific societies and the government research institutes.

The book appears to be designed as a contribution to current discussions on the increases of industrial productivity. It first briefly outlines the industrial pattern of Switzerland and the extent to which research is fostered in industry. This is followed by a chapter on the universities and industry, in which some comparison is made between Swiss and British universities, and the relations between industry and the universities in Switzerland are discussed. A chapter on institutions for co-operative industrial research makes good a gap; the remaining chapters deal with the Federal Government as a sponsor of research, and with research, taxation and the patent system, and finally Prof. Edwards attempts to outline the general influences in Swiss life that must be taken into account in seeking the root causes of Swiss industrial achievement.

One merit of this book is that, although it makes many suggestive comments on the differences between the pattern and practice of industrial research in Great Britain and in Switzerland, Prof. Edwards never attempts to push the comparison too far. He is fully aware of the differences in definition, for example, which may make comparison between one industry or one country and another misleading, even where figures exist as a basis. The chapter on the universities and industry may well prove to be the one of most general interest, and its account of science and technology in the universities has a bearing on discussions on higher technological education in Britain. It appears from the analysis presented here that, out of its relatively larger university population as compared with that of Great Britain, Switzerland has a higher proportion of students reading applied science and technology, and that the difference has become more marked since the Second World War. On the other hand, Great Britain spends more per student and the ratio of staff to student has increased slightly, whereas in Switzerland it has decreased appreciably since before the War.

Prof. Edwards's comparison between Switzerland and Great Britain is not unflattering to the latter; but it does not encourage complacency. He points to some weaknesses in the Swiss system, particularly in regard to fundamental research and the lack of openings in academic life. He suggests that a full-scale study of Swiss technical schools, and especially of the Federal Institute of Technology, their organization, administration, curricula and relations with industry, both in regard to training and research, would make a more important contribution to the current debate in certain circles in Britain on the future of technological education than a study of the relations between industry and the universities in the United States now being investigated by a team under the Anglo-American Productivity Council. The great problem, in his view, which Great Britain has not yet fully solved, is how to adapt middle and higher education to meet the needs of the large number of students who must find—and who it is hoped will want to find—their careers in the middle and upper ranks of industry and trade. Prof. Edwards does not claim that his present essay is more than a sketch. Whether or not it stimulates the further inquiry he suggests, it should at least assist in keeping on a factual and practical basis future discussions on productivity and on technological education.

R. BRIGHTMAN

Physical Chemistry

By A. J. Mee. Fourth edition. Pp. xix+753. (London: William Heinemann, Ltd., 1951.) 25s.

THIS well-written book has for years been recognized as a standard introduction to physical chemistry for university students. By resetting the type and by some rearrangements, the publishers have shortened the book by twenty-nine pages: otherwise there is very little alteration from the 1947 edition. The new matter amounts in the aggregate to two pages only; of these, one page is given to chromatography and the other is made up of some additions to a few chapters each too small to be of much value. Further, the author has deleted two adversely criticized pages dealing with the theory of ionic discharge and has not filled the gap. With the uneven advance of knowledge this policy of leaving well alone is highly questionable. For example, the small and unchanged section devoted to artificial radioactivity is now out of all proportion to the very numerous papers appearing on this subject. Again, as the author has left his discussion of nuclear fission unchanged from 1947, he still makes no mention of plutonium and neptunium, of Powell's work on mesons, of the production and use of radioactive tracers, or of polarography. Accordingly, it is astonishing to read the publishers claim that the book has been "revised throughout" and that the treatment of nuclear fission is "up-to-date". Finally, throughout the book the bibliographies are now behind the times.

G. Fowles

Intermediate Practical Chemistry

By Sylvanus J. Smith. Pp. vii+248. (London: Macmillan and Co., Ltd., 1951.) 8s. net.

TO the text-books already to his credit Mr. S. J. Smith has now added a complete practical chemistry intended for the advanced course in schools and for classes of a similar standard. In selection and treatment the author keeps mostly to the classical tradition; but he occasionally introduces a novelty. Thus in the section on volumetric analysis (83 pages), students are encouraged to prepare standard sodium carbonate by a laboratory modification of the Solvay process. Mr. Smith gives 21 pages to gravimetric and colorimetric analysis, and 35 pages to physical chemistry; organic chemistry, mostly preparations, gets 55 pages and qualitative analysis 52. An appendix contains directions for the preparation of reagents and a table of logarithms. The scheme contains more experiments than can usually be done in a school course, but does not contain any on the colloidal state, or on the determination of gas-volume ratios, and few on inorganic preparations. Still, the book contains a good course of work, and the author is obviously an experienced teacher who knows the limitations of a school laboratory.

Inorganic Syntheses

Editor-in-Chief, Ludwig F. Audrieth. Vol. 3. Pp. xi+230. (London: McGraw-Hill Publishing Co., Ltd., 1950.) 32s.

THIS volume continues a series intended to provide chemists with a compilation of tested methods for the synthesis of inorganic compounds. Any such series is likely to have the limitation evident in this volume—that it provides only for a restricted number of specialists in particular fields of research. The wide variety of techniques common in modern inorganic chemistry tends to bring discontinuity into any text covering selected compounds rather than chosen experimental methods.

In addition to a number of specially selected single substances, this volume covers several interesting groups of inorganic compounds such as alkali phosphates and fluo-phosphates, a number of anhydrous metal fluorides, and several organo-silicon derivatives. The special techniques required for the preparation of strontium sulphide and selenide phosphors are fully detailed, and a particularly interesting section outlines the extraction and separation of zirconium and hafnium from cyrtolite. Further sections deal with the preparation of boron trichloride and tribromide, rendered particularly difficult by the ease of hydrolysis of these compounds.

The descriptive detail of this volume maintains the high standard set by volumes 1 and 2, and the whole work gives evidence of careful selection and testing of the prescribed methods. It is a worthy addition to any reference library, although the frequency of its use will largely depend on the particular interests of inquiring readers. The book also provides useful material for a neglected aspect of university work—the teaching of preparative inorganic chemistry.

Inland Waterways of Great Britain and Northern Ireland

Compiled by Lewis A. Edwards. Pp. xvi+440. (London: Imray, Laurie, Norie and Wilson, Ltd., 1950.) 30s.

THIS book contains much valuable and detailed information about the canals and rivers of Great Britain and Northern Ireland. The bulk of the text consists of an alphabetical account of each canal and river at present open to navigation, giving areas served, distances, maximum dimensions for craft using the waterway, speed regulations and other information essential to users. In addition, there is a valuable appendix containing short sections on such matters as the history of inland waterways, locks and lifts, aqueducts, bridges and types of commercial craft. There are also navigation hints, tides and tidal information and a list of rivers suitable for canoeing. Particularly useful is the glossary of canal terms, with its definitions ranging from the so-frequently misused term 'barge' to 'chalico' (the mixture used for dressing the timbers of wooden boats) and to the 'gongoozler' (an idle and inquisitive person who stands staring for long periods at anything out of the common).

In a foreword, Mr. R. F. Aickman, chairman of the Inland Waterways Association, stresses the point that the two thousand miles of navigable river and canal in Great Britain offer unlimited possibilities for pleasure traffic, and argues that what has been done on the Norfolk Broads can be done throughout the country.

Under the provisions of the Transport Act, 1947, our navigable rivers and canals have become national property, and the great interest now taken in the possibilities of using these waterways for pleasure traffic, together with the efforts of the Inland Waterways Association, is leading to considerable developments. In addition, it is clear that local water shortages, coupled with serious flooding in many areas, make the maintenance and improvement of the inland waterways of Great Britain a national necessity.

THE DEVELOPMENT OF TAXONOMIC THEORY SINCE 1851*

By J. S. L. GILMOUR

Director, University Botanic Garden, Cambridge

THE early 1850's as a starting point for the examination of the development of taxonomic theory are appropriate not only because of the centenary aspect of the Edinburgh meeting of the British Association but also because they have an intrinsic importance as the culminating point of pre-Darwinian taxonomy, when the natural system had triumphed completely over the Linnean. What basic assumptions, then, were held by taxonomists at this period ? What, to put it crudely, did men like Robert Brown and William Hooker have at the back of their minds when they described one of their countless new species, genera or families ? A good answer can be obtained from John Lindley's preface to his "Natural System of Botany" (1836).

Lindley's basic concept was that of natural affinity. He looked upon classification as a process of discovering such affinity between different species, the degree of affinity being measured by the degree of resemblance. The concept of affinity itself is nowhere specifically defined ; but it is clear, I think, that Lindley did not regard it as identical with degree of resemblance, but rather as something distinct which was indicated by resemblance. In so far as Lindley did attempt to characterize further the concept, he linked it with the then commonly held belief in the existence of a plan of creation laid down, once and for all, by a Creator, and he regarded affinity between species as, in some way, an expression of such a plan. He was, however, not altogether whole-hearted in his support of this view. "We must suppose," he writes, "that one plan only has been observed in the creation of living things, and that a natural system is the expression of that plan." Immediately afterwards, however, he qualifies this by adding that "it must not be forgotten that such a plan may be represented in many ways". This gave scope for his strongly held conviction that, above the rank of species, which he regarded, of course, as fixed and unchanging, taxonomic categories are man-made, and that it is quite impossible for us ever to construct one universally agreed natural classification, not only because of our varying degree of skill in the recognition of affinity but also because species are connected in, so to speak, many different planes, thus making it impossible to represent their relationship in a single, one-dimensional scheme.

We can take it that Lindley's concept of natural affinity, more or less modified, of course, as regards emphasis, was the generally accepted assumption underlying biological classification immediately before Darwin, in 1859, put forward his theory of evolution based on natural selection. Before considering the effects of Darwin's work, I would like to point out, in passing, that the natural affinity concept inevitably placed biological classification in a category quite apart from the classification of non-living things and that there was very little attempt at that time, by biologists, to consider what common principles, if any, there might be between the classification of, say, books on one hand and buttercups on the other.

As is well known, the acceptance of evolution led Darwin himself, and taxonomists in general, to give a new meaning to natural affinity. Lindley's rather vague and mystical concept was re-interpreted in evolutionary terms, and identified with what was variously described as genealogical relationship, phylogenetic relationship, true relationship, or simply relationship. Darwin himself, for example, in the famous Chapter 14 of the "Origin of Species", laid down that all true classification is genealogical and that "community of descent is the hidden book which naturalists have been unconsciously seeking", and the majority of later taxonomists have taken the same view. George Bentham, for example, in his address to the British Association in 1874, on "The Recent Progress and Present State of Systematic Botany", expounds it at length, and most modern text-books echo the same interpretation. Dr. Swingle, for example, in his "Text Book of Systematic Botany" (1946) writes : "The *ideal* classification . . . must show actual phylogenetic relationships", and many other similar expressions of this view could be quoted.

Interrupting and disturbing, however, this stream of doctrine flowing from the "Origin of Species", there have been an increasing number of rocks and islets of opinion which have criticized, in one way or another, the simple identification of Lindley's natural affinity with post-Darwinian 'relationship'. Such criticism has not, of course, been directed for one moment against either the fact that evolution has taken place, or that genealogical relationship is clearly one of the prime factors influencing similarity between living organisms. The criticism, rather, has been directed against the over-facile picture that has been built up of the existence of one single, vast, phylogenetic tree of living organisms, analogous with a genealogical family tree of individuals, and against the view that the prime and ultimate aim of taxonomy is to discover and embody this tree in one ideal system of biological classification. Many botanists and zoologists have shared in this critical attack ; but I have space to mention only F. A. Bather's masterly analysis in his address to the Geological Society of London in 1927 on "Biological Classification, Past and Future", and W. B. Turrill's comprehensive survey in *The Botanical Review* of 1942. Further, those who took part in the Systematic Association's discussions just before the War on this subject will not easily forget the arguments put forward on both sides, nor the heat they engendered, and this year at Leeds the battle was joined again under the auspices of the same Association (see *Nature*, 167, 503 ; 1951).

What, then, has been the substance of these criticisms ? Broadly speaking, they have emphasized the extreme complexity of evolutionary change, the impossibility of extracting from the welter of actual evolutionary history (including polyphyletic origins in both time and space) any single, simple factor that can be called genealogical or phylogenetic relationship, and the folly, even if such a factor could be isolated, of regarding morphological resemblance as an exact index of it.

---

* Substance of a paper read on August 14 before Section K (Botany) of the British Association meeting at Edinburgh.

There is no doubt, to my mind, that such criticism is amply justified, but I would like to suggest that it has somewhat misfired owing to the lack of any positive proposal put forward as an alternative to the admittedly very attractive and simple picture of one ideal classification based on "true relationship".

To understand the reason for this lack of alternative we must go back, for a moment, to Lindley and the pre-Darwinian taxonomists. Their concept of natural affinity, expressing the plan of a Creator, lifted biological classification right out of the realm of the classification of non-living things, and the Darwinian re-interpretation has, of course, further emphasized this separation. The fact is, however, that biologists have almost completely ignored, or dismissed as irrelevant, the fundamental principles of classification which apply to all objects, whether living or non-living, and which have been discussed and re-discussed by philosophers from the time of the Greeks until the present day. This isolation of biological from general classification has, in my view, been fatal to a proper appreciation of the aims and methods of taxonomy and is largely responsible for the confusion that exists to-day.

These general principles may be studied in many text-books of philosophy and scientific method. Perhaps the most satisfactory for our purpose is "The Principles of Science" by W. S. Jevons, first published in 1874. From this and other sources the following highly simplified elementary principles may be extracted.

(1) Classification is a fundamental prerequisite of all conceptual thought, whatever the subject material of that thought. Thus, as soon as we call an object 'hot', we are creating a class of hot things and assigning the object to that class.

(2) The primary function of classification is to construct classes about which we can make inductive generalizations. Thus, having constructed the class of hot things, we construct a further class of 'things that hurt', and, based on experience, we can make the inductive generalization that hot things hurt.

(3) The particular classes we construct always arise in connexion with a particular purpose. The class of 'things that hurt' clearly springs from a universally important purpose to human beings—the avoidance of suffering; the class of, say, "botanists whose fathers had beards", does not, and hence has not, so far as I know, been constructed before this moment.

(4) The classification that we adopt for any set of objects depends on the particular field in which we wish to make inductive generalizations. Different fields of generalization call for different classifications. Thus, if we wish to investigate the connexion between female authorship and murder stories we would make quite a different classification of books from that required for generalizations about, say, American publishers and limited editions.

(5) Clearly some classifications are of more general use than others. Thus a classification of books, based on subject-matter, into such classes as dictionaries, novels, biographies, etc., is of wider use than one based on the colours of bindings. The reason for this is that the basis of the first classification, namely, the contents of the book as conceived by the author, affects more of its characteristics than does the basis of the second classification, namely, the colour of the book as conceived by, presumably, the publisher. In short, subject-matter has a stronger influence on the total characteristics of books than has binding design. In the general theory of classification, classifications which serve a large number of purposes are called natural, while those serving a more limited number of purposes are termed artificial.

(6) It is clear from the above that there cannot be one ideal and absolute scheme of classification for any particular set of objects, but that there must always be a number of classifications, differing in their basis according to the purpose for which they have been constructed. One classification may, of course, be more natural than another in the sense defined above, and if there is one factor influencing a group of objects more powerfully than any other, then a classification based on that factor will be more natural—that is to say, useful for a greater number of generalizations—than any other; but the difference between this and other classifications is one of degree only, and not of kind. In the classification of books, for example, an arrangement based on subject-matter is probably more natural than any other, but one based on authorship must run it fairly close, bringing in, as it does, the factors of date and style, as well as, to some extent, that of subject-matter.

The view just outlined of the general nature and function of classification as a basic process in the making of inductive generalizations is the one generally accepted by students of scientific method. What is its relevance to biological classification? Its relevance is, I suggest, two-fold. In the first place, it can perhaps help us to understand more clearly the history of taxonomy, its aims and its methods, during the past hundred years; and, secondly, it can, I think, lead to a view of the aims of taxonomy more in line than at present with modern philosophical thought in general and more useful in solving some of the problems now confronting taxonomists—notably those problems concerned with the incorporation of recent data from experimental taxonomy into suitable taxonomic categories.

As regards history, we can see how a failure to appreciate the general principles of classification, and to apply them to living things, has led biologists to seek other aims for taxonomy in order to fill the vacuum created. The form which these aims have taken, namely, the construction of one ideal classification based, at first, on natural affinity and, later, on 'true relationship', is a particularly attractive one to the human mind. It has the comforting qualities of all 'absolutes', and the concept of true relationship undoubtedly bears, emotionally, a strong family resemblance to the concepts of beauty in æsthetics and goodness in ethics. Recently there has been a widespread element in philosophical thought tending to examine critically these absolute concepts in æsthetics and ethics, and I suggest that the time has come for the same healthy breeze to be directed towards the concept of true relationship in taxonomy.

This brings us to our second point of relevance. Let us suppose, for a moment, that we have abandoned as chimærical the aim of constructing one ideal classification of living things based on true relationship. What aim, grounded in the general principles of classification, can we put in its place, and how would such an aim help us to solve present problems in taxonomic practice?

Clearly, the primary aim of taxonomy, on this basis, must be the construction of classes of living things about which scientifically useful inductive generalizations can be made. Further, there must be a number of different classifications, each based on different characters, and each equally valid for its own purpose.

It is true that there will be one, as it were, general-purpose classification, more natural than others, in the sense that more inductive generalizations can be made about its classes—and this general-purpose classification is, of course, the normal taxonomic arrangement into species, genera, families and so on. This classification should not, however, be regarded as an approximation towards a single, ideal scheme, but as a permanently flexible arrangement, changing as new knowledge is acquired and incorporated in it. It can be called phylogenetic only in a secondary sense, namely, that the reason why a particularly natural biological classification can be made at all is of living things—and, further, phylogenetic studies can, of course, be made regarding the origin and development of its groups; but both these considerations are very different from regarding a natural classification as essentially and primarily phylogenetic.

One may well ask, what difference does it make in practice whether we regard a natural classification of living things as—to put it briefly—'logically' natural or 'phylogenetically' natural. Are we not just splitting hairs, with no practical result? I do not believe that this will prove to be the case. I believe it is possible that, if we can once and for all lay the bogey of the existence of true relationship and realize that there are, not one, but many kinds of relationship—genealogical relationship, morphological relationship, cytological relationship, and so on—we shall release ourselves from the bondage of the absolute in taxonomy and gain enormously in flexibility and adaptability in taxonomic practice. Instead of the present rigid separation between the normal categories on one hand and those of experimental taxonomy on the other, we shall realize that they differ in degree and purpose only, and are all equally valid for the overall purpose of making inductive generalizations about living things. To take a concrete example, Turesson's geneological classification and its later modifications, or Danser's categories of *Comparium*, *Convivium*, etc., based on capacity to interbreed, should not be regarded as possible rivals of the orthodox categories, but as special classifications equally valid for their own particular purposes. In the same way, a truly phylogenetic classification, based on known lineages, would also take its place as a special classification constructed for its own particular purpose.

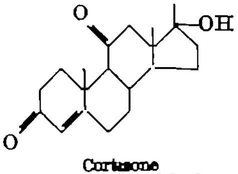
An ever-increasing volume of data is now being produced in the field of experimental taxonomy, data showing the great complexity of the units comprising the ebb and flow of evolutionary change. Recently, Dr. W. H. Camp, in a stimulating paper entitled "Biosystematy" (*Brittonia*, 7, 113; 1951), has emphasized forcibly the difficulty of fitting the dynamic concepts of modern experimental taxonomy into the orthodox categories of genus and species, conceived, as they were, against the static background of special creation. He hints that these categories may have to be abandoned completely for the special purpose of classifying the actual units of evolutionary change, and I would strongly support this view. Such a course would seem almost sacrilegious if we regard the orthodox taxonomic categories as an attempt at expressing 'true relationship'; but on the view that I have been outlining, that they are human contrivances constructed for human purposes, there is, of course, nothing shocking in abandoning them if they do not serve the particular purpose we have in mind at the moment.

I do not claim that what I have said here is more than the outline of an approach to present taxonomic problems, and I hope that others may be persuaded to join in working out its implications more fully.

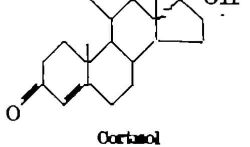
ORGANIC CHEMISTRY IN THE SERVICE OF MEDICINE

ONE of the sessions of Section B (Chemistry) of the British Association, during the recent Edinburgh meeting, was devoted to a symposium on "Organic Chemistry in the Service of Medicine." Notwithstanding the title, two of the three papers which were presented had a distinctly biochemical flavour, which perhaps serves to emphasize that organic chemistry and biochemistry are inextricably intermingled, in spite of those who would have it otherwise. The chair was taken by Prof. G. F. Marrian, who suggested that one of the main reasons for the selection of the subject of the discussion was a desire to honour the memory of the late Prof. George Barger, his predecessor in the chair of chemistry in relation to medicine in the University of Edinburgh. Prof. Marrian recalled some of Barger's outstanding chemical contributions to medical science, and referred also to the important work carried out by some of the pupils whom he inspired.

The first paper in the symposium was read from the chair by Prof. Marrian, who described recent work on the adrenocortical steroids. He pointed out that the discovery by Hench, Kendall and their collaborators of the treatment of rheumatoid arthritis and certain related diseases by cortisone, or by administration of the adrenocortical stimulating hormone of the anterior pituitary, no longer seems to be the great discovery in practical therapeutics that at first it appeared to be. But to the medical scientist, who takes a longer view than his clinical colleague, the discovery appears to be even more important than it did two years ago, on account of the way in which it has stimulated chemical, biochemical and clinical research on the adrenocortical hormones. The work of Kendall and Reichstein, and their collaborators, on the 'life maintenance' principle of the adrenal cortex, led to the isolation, during the period 1936–40, of six active steroids and to the determination of their structures. These are 11-deoxycorticosterone (now known as cortexone), corticosterone, 11-dehydrocorticosterone, and their respective 17-hydroxy derivatives. Two of the latter are cortisone and the related compound cortisol, both of which are therapeutically active in the treatment of rheumatoid arthritis. Cortisol is likely



Cortisone
(17-Hydroxy-11-dehydro-corticosterone)



Cortisol
(17-Hydroxy-corticosterone)

soon to be more readily available, and is believed to be preferable to cortisone in some respects.

Cortisone appears to influence rheumatoid arthritis and related diseases by suppressing the inflammatory symptoms in the mesenchymal tissues; this is in contrast with the function of adrenocortical hormones in the treatment of Addison's disease, where the effect is to make good a deficiency or absence of the endogenous hormones.

Prof. Marrian thought that, from a biochemical point of view, one of the most interesting and challenging facts about the adrenocortical hormones is the multiplicity of the physiological and pharmacological effects which they are able to produce. He suggested that there may be some common biochemical factor underlying these, possibly the interaction of the hormone with some particular chemical grouping which is present in a number of different enzymes. Several groups of workers have demonstrated effects *in vitro* of some of the hormones on the carbohydrate metabolism of preparations of liver and muscle tissue. It has also been found that granulation tissue from healing wounds or embryonic tissues maintained *in vitro* are able to fix sulphate in insoluble organic combination, possibly due to the synthesis of sulphated mucopolysaccharides. This fixation of sulphate can be entirely inhibited by the addition of cortisone to the culture medium. Another group of workers has found that hyaluronidase can be inhibited by cortisone.

One of the most outstanding recent achievements has been that of Pincus and his collaborators, who have shown conclusively, by using cholesterol labelled at C_4 with carbon-14, that under the influence of adrenotrophic hormone the adrenal gland is able to manufacture the adrenocortical hormones by degradation of cholesterol. By using various steroids these workers were also able to show that the gland (without adrenotrophic hormone) can effect hydroxylation at positions 11, 17, and 21, and they obtained evidence that progesterone is an intermediate in the conversion of cholesterol to the adrenocortical hormones. Thus progesterone, which has been isolated from the adrenal gland, was converted into corticosterone and cortisol.

In conclusion, Prof. Marrian referred to current work aimed at the total synthesis of cortisone, which may conceivably satisfy the requirements of the hormone for clinical use. He recalled the recently announced total synthesis of *epi*androsterone by Sir Robert Robinson and his collaborators, an achievement which also represents the total synthesis of androsterone and testosterone. Almost simultaneously, Woodward and his collaborators announced the total synthesis of the methyl ester of *dl*-3-keto-$\Delta^{4,9(11),16}$-*aetio*cholatrienic acid. This has since been resolved and converted into cholestan-3β-ol, which had already been converted into cholesterol. Among other steroids the total synthesis of which has been completed by this work is the adrenocortical hormone cortexone (the total synthesis of cortisone has also just been reported (Woodward *et al.*, *J. Amer. Chem. Soc.*, 73, 4057; 1951)).

Dr. F. L. Rose followed with an interesting and authoritative account of the extensive co-operative researches carried out during the Second World War on the synthesis of new antimalarial drugs. The most outstanding advances in this field were those of Dr. Rose himself and the late Dr. F. H. Curd and their collaborators, culminating in the discovery of the most effective antimalarial drug so far known, namely, 'Paludrine'. The importance of this service to medicine and to mankind may be gauged by Prof. Marrian's comment that it has been estimated that a quarter of the population of the world suffers from malaria. In his contribution, Dr. Rose pointed out that malaria is unique among the diseases of micro-organismal origin in that it has a history of chemotherapy extending over the past three hundred years, arising from the use of the cinchona alkaloids. Quinine is not the perfect antimalarial drug, however, and the search for improved synthetic agents began in the past century. Dr. Rose showed how the observation by Ehrlich and Guttman in 1891 of the slight therapeutic effect in man of methylene blue opened the way for future developments. Exploitation of this early lead was delayed until new preparations, based on this dyestuff, could be assayed in the laboratory. This came in the early part of the present century with the discovery and use of the avian malarias. By then, the significant features of the structure of quinine had become clear, and this knowledge led in 1926 to the synthesis in Germany of the related 6-methoxyquinoline derivative pamaquin (originally called 'Plasmoquine'). The continued search for a drug having schizonticidal activity resulted, a few years later, in the acridine derivative mepacrine ('Atebrin'), and it was this substance that was selected for process study in Britain in 1938 as an insurance against a break in quinine supplies resulting from war, which then seemed imminent. At that time, the use of mepacrine was still in the experimental stage, and although its availability from 1940 onwards was of vital military significance, careful clinical investigations established its limitations and disadvantages. As a result, intensive co-operative searches for new and improved agents were begun, co-ordinated in Great Britain by the Medical Research Council, and in the United States by the National Research Council. The objectives were freedom from colour (skin pigmentation) and reduced toxicity, ease of manufacture, and an action at the exoerythrocytic phase of the life-cycle of the causative parasite. This last had by the early 1940's assumed paramount importance in the minds of workers looking for new antimalarial drugs, since only through the control of the tissue forms could true causal prophylaxis be obtained.

A vast screening programme in the United States dealt with some fourteen thousand compounds, and led to the discovery of antimalarial activity in experimental infections (including prophylactic action) in a number of previously unconsidered chemical types. The most important outcome of this search was the establishing of the therapeutic value of the 4-aminoquinoline derivative chloroquin, a substance which under its name 'Resochin' is now known to have been undergoing field-trials at the hands of its German discoverers in 1939.

In Britain, a more modest programme led to the preparation and assay of, perhaps, two thousand substances in all. The majority of these were based on the discovery, early in the work, of laboratory activity in a chloroanilinopyrimidine. Exploitation of this lead also resulted in the elaboration of a wide variety of compounds, mostly heterocyclic, exhibiting similar behaviour, of which one at least, *p*-chlorophenylguanidinopyrimidine, was active clinically. An attempt to get away from the use of heterocyclic systems, while yet retaining other features considered structurally significant, led in 1944 to an investigation of certain diguanide derivatives. These proved active, not only against erythrocytic but also against the exoerythrocytic forms of the experimental avian parasites, and one such derivative, proguanil ('Paludrine': N^1-*p*-chlorophenyl-N^5-*iso*propyldiguanide), has passed into extensive clinical use on this basis.

As a result of these war-time endeavours, the objectives initially postulated have been largely attained. The causative organisms of malaria are so numerous in variety and drug susceptibility, however, that some forms of the disease inevitably remain resistant to therapy if only in degree, and the existence of these, together with the problem of relapse in certain cases, provide the challenge for the future.

In the concluding paper of the session, Mrs. R. V. Pitt-Rivers described recent work on the thyroid gland. She pointed out that the biosynthesis of thyroxine depends on the ability of the thyroid gland to collect iodide from the plasma and to fix it in organic combination. In the normal animal, the iodine-concentrating mechanism is largely controlled by the thyrotrophic hormone of the anterior pituitary, and fails in hypophysectomized animals. Thiocyanate inhibits the iodine-concentrating mechanism and, in fact, causes the discharge of iodide already collected by the gland. The second function of the thyroid, the synthesis of thyroxine, is generally assumed to occur in three stages: (*a*) oxidation of iodide to iodine, (*b*) iodination of tyrosine, and (*c*) coupling of two molecules of diiodotyrosine. The first stage requires enzymic activity, but this is not necessarily so for the coupling reaction, as coupling can occur *in vitro* in the absence of any enzyme system. Dr. Pitt-Rivers has found that if the amino group is protected by acylation and the carboxyl group by peptide combination, then the yield of thyroxine formed by incubating diiodotyrosine aerobically can be raised to 35 per cent. The coupling is an oxidative one, but its mechanism is not known, nor is the fate of the three-carbon chain which is lost from one molecule of diiodotyrosine.

Dr. Pitt-Rivers outlined experiments with antithyroid drugs of the thiourea group and also with aniline derivatives which include *p*-aminobenzoic acid and some of the sulphonamides; these have led her to conclude that the formation of thyroxine from diiodotyrosine is an oxidative reaction brought about *in vitro* by small amounts of iodine liberated from the diiodotyrosine. In *in vivo* experiments, too, the formation of thyroxine is invariably accompanied by loss of iodine from diiodotyrosine. The remarkable inhibition of thyroid function by iodide is possibly due to an inhibition by excess of iodide of the enzyme system which is responsible for its own oxidation.

Finally, Dr. Pitt-Rivers showed how the use of new techniques, in particular the use of radioactive iodine and partition chromatography, has enabled several groups of workers to localize reactions in which iodine plays a part, and to detect iodo compounds which are present in the gland only in traces. Apart from diiodotyrosine and thyroxine, the only iodine compound present in the gland which has been unequivocally characterized is monoiodotyrosine. All three compounds are present in the thyroid in very small amount as free amino-acids, and three new iodine-containing compounds of unknown constitution have been detected in the gland. Evidence has been provided that the circulating hormone in the plasma is free thyroxine.

AUTOMATIC CONTROL

A CONFERENCE organized by the Department of Scientific and Industrial Research, on the subject of developments in the field of automatic control, was held at the College of Aeronautics, Cranfield, during July 16–21, under the presidency of Sir Ben Lockspeiser. It was attended by some three hundred engineers, mathematicians and teachers of engineering, including members from most of the leading industrial countries.

The purpose of the present article is to give an impression of the state of developments in the field of automatic control as revealed by the papers and the discussion at the conference. The broad principles of automatic control involving feed-back are now very well known, and many useful methods for the analysis of the behaviour of control systems are quite familiar. The conference was concerned with those aspects of the subject that go beyond these well-established principles and methods and in which further progress is required. The chief topics may, perhaps, be broadly classified as follows: first, educational problems arising from the growing importance of feed-back systems, and the rapid increase in the demand for personnel having specialized knowledge and skills in this field at all technical levels; second, the development and co-ordination of improved methods of mathematical analysis for such systems; third, the extension of the methods to a widening range of technical and other problems; and finally, the attempt to deal more adequately with such problems as systems with non-linearities and with intermittent data. In attempting to give a summary of the present state of progress as revealed by the conference, it will be convenient to consider these four topics in turn.

Educational problems. New requirements in respect of instruction in the principles of automatic control are arising over the whole educational spectrum, from the shortage of instrument mechanics in the chemical industries to the need for more men of the highest engineering and mathematical competence to carry on development work in such fields as the control of aircraft or the development of combined analogue-digital calculators.

The opening paper of the conference by Prof. Gordon Brown, of the Massachusetts Institute of Technology, made a striking plea for the recognition of the "feed-back engineer" as a new professional category corresponding with a new type and perhaps a new standard of professional competence. The specification for a feed-back engineer is for a man capable of synthesizing many technical specialisms and capable of eliciting co-operation at all technical levels. Prof. Brown described the postgraduate school in control engineering at the Massachusetts Institute of Technology, which has an annual output of approximately fifty postgraduate students. This figure was referred to by a member from a leading American instrument firm as "merely a drop in the ocean of America's requirements". Prof. Brown described how students are trained at the Massachusetts Institute as working engineers participating in large-scale research projects, accepted by the Institute on contract. Such forms of advanced technical training are unknown in Great Britain, where it is noteworthy that the research establishments of government departments and of the research associations have no specific educational functions and not even in organized liaison with higher education.

Progress in methods of mathematical analysis. The analysis of the behaviour of linear systems with feed-back corresponds with the discussion of the implications of a set of simultaneous linear differential equations. Since complex as well as real roots are in question this naturally leads to representation on the complex plane. The types of analysis that have been developed for application to feed-back amplifiers, networks and filters are generally applicable to linear automatic control systems. Developments now being made in this type of analysis, as indicated by one group of papers presented at the conference, may be described as the exploration of the geometry of poles, zeros and 'transfer loci' on the complex plane, in the attempt to obtain various kinds of information about the behaviour of the system, such as its modes, their kind and degree of damping, and the conformity with various criteria of stability and minimum error. A particularly interesting development arises from the fact that the functions involved are usually regular functions, and such functions of a complex variable have a correspondence with the flow-lines and equipotentials for current flow in a conducting sheet. This fact has been ingeniously exploited by A. R. Boothroyd and J. H. Westcott, who described and demonstrated the use of the electrolytic tank as an analogue interpreting a logarithmic transformation of a complex variable, by the use of which the design of both control systems and filters may be facilitated.

An important problem requiring distinct treatment arises when control systems are subject to random disturbances. Two papers, respectively by M. J. Pélégrin and S. Jones, dealt with the application to control systems of the method based on statistical ideas and correlation that was originally developed by Wiener.

The view was expressed by several contributors that, important as these improvements in analysis may be, they must, by their nature, be deficient in meeting the basic problem of the selection and design of control elements, because they do not bring under consideration the physical limitations of the elements that are essentially related to power handling and the interchange and flow of power. One paper only grappled with this problem of relating the design of machine elements to the specified power amplification and the limitations of rating. This was the paper by J. M. Layton, in which some useful first steps are taken in this direction, by introducing the relationship that arises between the time constants and the power amplification in any element (such as an electric generator) in which there is energy storage proportional to the power output.

Extension of control system theory to a wider range of problems. One of the most important and rapidly expanding fields for the application of automatic regulation and control is the chemical and process industries. A complete day of the conference was devoted to this field. This was deliberately placed in the middle of the conference programme, because the organizers thought that one of the needs of the moment is to throw 'process engineers' and 'servo engineers' into intimate contact. This plan resulted in a vigorous discussion, somewhat hampered by difficulties of language, and by the unfortunate fact that each party appears to the other to plot all its diagrams back to front and for the inverse variable. It may be unfortunate that those now attempting to establish standardization of terms have abandoned the effort to reconcile those of process engineering with those of 'servos', and propose to perpetuate the differences. Perhaps a few years of delay and more such joint meetings would convince both parties that a common nomenclature would be both possible and useful.

The papers presented under the general heading of process control dealt mainly with the calculation and measurement of the transfer functions of pneumatic controllers and of plant elements such as pipe-lines and heat exchangers, in a form that permits of the use of this information in the familiar 'frequency-response' type of analysis.

Automatic-control principles are constantly finding application in new and somewhat surprising contexts. For example, A. Garde, of Stockholm, described an experimental investigation of the response of frequency to power load for a complete power system that involved the artificial imposition of a sinusoidal variation of power of 15 MW. as the test signal.

The theory of control systems is mainly a discussion of systems in which a number of variables, often a large number, are interdependent or inter-related, that is, some of the sequences of dependence are closed. This situation arises in many scientific fields, and when it is required to discuss the behaviour of such systems the methods of the theory of control systems may be useful. A good example is in economics, where much recent work concerns the implications of given inter-relationships between 'macro-economic' variables such as total income and total investment. This topic was the subject of an informal evening lecture given by J. R. N. Stone, of Cambridge, with a short addendum from an engineer's point of view by Prof. A. Tustin. It was urged that the interpretation of the implications of the rather complex 'models' necessary to give adequate representation of an economic system might be assisted by the use of physical analogues, as is often done in the case of complex engineering problems.

Special problems : intermittent data and non-linear systems. Groups of papers were devoted to the two chief aspects of control system analysis which the usual linear theory omits.

The first type of problem is that in which the system may be linear in the sense that it satisfies the principle of superposition, but where the operation is essentially discontinuous. One familiar example arises when 'clamped' or 'chopper bar' regulators are used, that measure a continuous variable at fixed equi-spaced instants, but between these instants merely hold or 'clamp' the value from the preceding measuring instant. A very analogous problem arises when incoming data is in digital form, giving effectively the value of a set of equi-spaced ordinates of the input curve. The handling of such problems will be greatly facilitated by papers included in this conference. The contributions by Prof. C. Holt-Smith, D. Lawden and A. E. Bailey, and the papers by Dr. R. C. Oldenbourg and Dr. H. Sartorius from Germany, make a noteworthy advance on previous work.

One day of the conference was given to the different problems that arise when systems are non-linear. Among those present for this discussion were such well-known authorities as Prof. B. van der Pol, Dr. N. Minorsky and Dr. Mary L. Cartwright, and the discussion was on a high level even if it mainly showed once more the unfruitfulness, so far, of attempts to deal with most non-linear systems except to seek specific numerical solutions to specific problems. A possible point for future progress lay in the paper by C. Cherry, in which he returned to fundamentals, and showed by adapting the equations of Lagrange that in certain systems the part played by energy in linear systems is played by areas under a curve in the case of non-linear systems.

Manual-control as distinct from automatic control was not forgotten. The paper on this subject by J. D. North included a thorough analysis of a 'model' that may provide a useful approximation for the response of hand to eye in some simple situations such as target tracking or car driving.

The discussions throughout the conference were vigorous and sustained. It appeared to be the opinion of all who attended that the conference has helped to lay foundations on which much further progress may now be based.

The papers presented, together with selected material from the discussions during the conference, will be published in due course as a single volume by Butterworths Scientific Publications, Ltd.

A. Tustin

STRUCTURE OF RIBONUCLEIC ACID

By Dr. ROY MARKHAM and Dr. J. D. SMITH

Agricultural Research Council Plant Virus Research Unit,
Molteno Institute, University of Cambridge

In the past few years the basic constitution of several ribonucleic acids has been established[1-4], but so far there has been little evidence as to the way in which the constituent nucleotides are arranged in the molecules. Hydrolysis of ribonucleic acids by alkali and by cold dilute acids gives rise to isomeric nucleotides which are probably 2′ and 3′ nucleoside phosphates[5-7], and Cohn and Volkin[8] have recently also identified 5′ nucleoside phosphates in ribonucleic acids digested successively with both ribonuclease and alkaline phosphatase. In the work which we propose to describe, we have attempted to isolate the larger fragments produced by ribonuclease action, and we have succeeded in establishing the structure of certain of the dinucleotides which were formed.

Anhydrides of the Pyrimidine Nucleotides

In our investigation of the products of digestion of ribonucleic acids, our attention was drawn at once to the presence of two substances which we have called *C* and *U*[9]. These substances are digested slowly by ribonuclease to give free cytidylic and uridylic acids respectively, and each contains one atom of phosphorus per pyrimidine residue. They differ from the nucleotides in that they have higher R_F values in 70 per cent v/v *iso*propanol–water–ammonia (solvent *a*), and lower R_F values in 80 per cent saturated ammonium sulphate in water, 2 per cent *iso*propanol, 18 per cent *M* sodium acetate (v/v/v) (solvent *b*). These properties led us to believe that they contained less free hydrophylic groups than exist in the corresponding nucleotides, possibly because they were dinucleotides or dinucleoside pyrophosphates. When we were doing this work, we were fortunate in having a discussion with Prof. A. R. Todd and Dr. D. M. Brown, and they were kind enough to disclose their theory of the formation of the isomeric nucleotides of Carter and Cohn. This theory[7] necessitates the existence as intermediates during the chemical hydrolysis of ribonucleic acids of cyclic anhydrides of the nucleotides, which have the phosphoric acid residue esterifying the ribose at positions 2′ and 3′. Such substances would have the properties of our *C* and *U*, and, in addition, would have the same electrophoretic mobilities as the corresponding nucleotides at *p*H 3·5, as do *C* and *U*, while, as we will show, the electrophoretic mobility of a dinucleotide should be about 1·54 times that of a mononucleotide having the same constituents. Synthetic samples of the anhydrides of cytidylic and uridylic acids prepared by Mr. D. Magrath were chromatographed by us in several solvent systems and could not be distinguished from *C* and *U* in any of these, while they too were digested slowly by ribonuclease to give the free nucleotides. It seems very likely that *C* and *U* are the 2′, 3′ anhydrides of cytidylic and uridylic acids respectively. The analogous adenine derivative was not digested by ribonuclease, and it seems probable that the guanine derivative is also resistant to digestion.

Free Nucleotides and Polynucleotides

For preparing these substances we have digested purified yeast ribonucleic acids with ribonuclease in dialysis sacs at 20° and also at 4° with stirring, so that any fragments liberated should have a chance to escape further digestion. After concentration *in vacuo*, the dialysate has been chromatographed in solvent *a* on Whatman No. 3 paper in bands. The developed chromatograph shows a residue at the top (band 0) and six main bands numbered 1–6 in order of their R_F values. Band 6 contains *C* and *U* only. Bands 1, 2 and 3 contain compounds of all four bases, while bands 4 and 5 have no guanine derivatives. Band 4 contains only adenylic acids *a* and *b*, cytidylic and uridylic acids. Free guanylic acids *a* and *b* are found in band 2. Bands 3 and 5 contain substances having properties similar to *C* and *U*; that is, they are digested by ribonuclease to give substances running faster in solvent *b* and slower in solvent *a*, but without changing their gross analytical composition. The analyses, however, show that each band contains several substances, as the purine and pyrimidine bases are not present in simple proportions.

Electrophoretic Separation

After trying without success a number of solvent systems for separating the substances in each band, we decided to try electrophoresis on filter paper strips, immersing the wet filter paper in carbon tetrachloride to cool it and to prevent evaporation. Strips of Whatman No. 3 paper 56 cm. long and 8 cm. wide were used, and the material was applied about 12 cm. from one end. A voltage gradient of 20–25 V./cm. was used and the average run was two hours (Fig. 1).

Before attempting the separation, we calculated the probable relative electrophoretic mobilities of all mono-, di-, and some tri-nucleotides at several *p*H values, using the dissociation constants of Levene and Simms[10], assuming that the mobilities were proportional to the net charge on the molecule, and inversely proportional to the cube root of the molecular volumes, a relationship which should hold to a close approximation in the case of such asymmetrical molecules, and which has been found to hold with some minor deviations in practice. The

CALCULATED ELECTROPHORETIC MOBILITIES TOWARDS THE POSITIVE ELECTRODE OF ALL THE MONO- AND DI-NUCLEOTIDES AND SOME OF THE TRI-NUCLEOTIDES AT pH 8·5, RELATIVE TO THAT OF URIDYLIC ACID
The symbols *A*, *G*, *C* and *U* signify the presence in the compound of one residue of adenylic, guanylic, cytidylic and uridylic acid respectively. The order in which they appear is not significant.

Mononucleotides		Dinucleotides		Trinucleotides	
C	0·16	*CC*	0·25	*ACC*	0·54
A	0·46	*AC*	0·48	*AAC*	0·75
G	0·95	*AA*	0·71	*GCC*	0·88
U	1·00	*GC*	0·85	*ACG*	1·09
		CU	0·89	*ACU*	1·13
		AG	1·08	*AAG*	1·30
		AU	1·18	*AAU*	1·33
		GG	1·46	*AGG*	1·64
		GU	1·50	*GCU*	1·67
		UU	1·54	*AUU*	1·71

order of movement that we calculated for pH 3·5 (M/20 ammonium formate buffer)—the value which we selected as optimum for our purposes—is shown in the accompanying table. At this pH the mobility is decided entirely by the primary phosphoric acid —OH⁻ groups and the —NH₃⁺ groups of the bases, and therefore anhydrides of the type of *C* and *U* and their derivatives will move at approximately the same speed as the corresponding nucleotides and their derivatives.

On electrophoresis, bands 1, 2, 3 and 5 are each found to contain at least three or four major constituents, most of which have been identified provisionally, while several of these substances have been submitted to analysis and have been found to have simple compositions. Among the latter are the dinucleotides of adenine and guanine, adenine and cytosine, guanine and uracil, and guanine and cytosine. These substances are found in bands 1 and 2 and are not attacked by ribonuclease; but there are also substances having the same composition with regard to the bases as the last three of these dinucleotides, but occurring in bands 3 and 5. The latter are digested by ribonuclease to give the dinucleotides only. As an example of this we can take the guanine–uracil dinucleotide of band 1. This substance can be isolated in a pure state from band 1 by electrophoresis, and is the fastest moving component of this band, having a *gross* mobility of 1·1 × 10^{-4} cm.^{2} sec.$^{-1}$ volt^{-1}. In band 3 there is a substance which also has one equivalent of guanine to one of uracil and has a mobility of 1·3 × 10^{-4} cm.^{2} sec.$^{-1}$ volt^{-1} (this difference is not significant). The substance from band 3 is converted into the dinucleotide of band 1 slowly by ribonuclease digestion. This digestion is not splitting a tetranucleotide, as such a compound would have a mobility of about 2 × 10^{-4} cm.^{2} sec.$^{-1}$ volt^{-1}, nor, of course, is any phosphorus liberated. Similarly, the adenine–cytosine dinucleotide of band 5 is converted by ribonuclease to that in band 2, as is the adenine–uracil dinucleotide of band 5; and all these digestions also cause the resulting dinucleotides to have higher R_F values in solvent *b*.

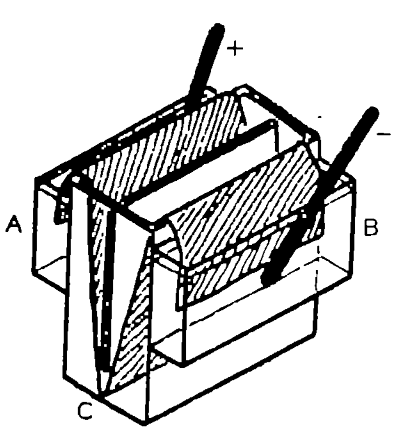


Fig. 1. Electrophoresis apparatus. Vessels *A* and *B* contain the buffer solution. Vessel *C* contains carbon tetrachloride, and in use is covered with a piece of plate glass. The wet paper is spaced in vessel *C* by a piece of celluloid. The electrodes are arc carbons

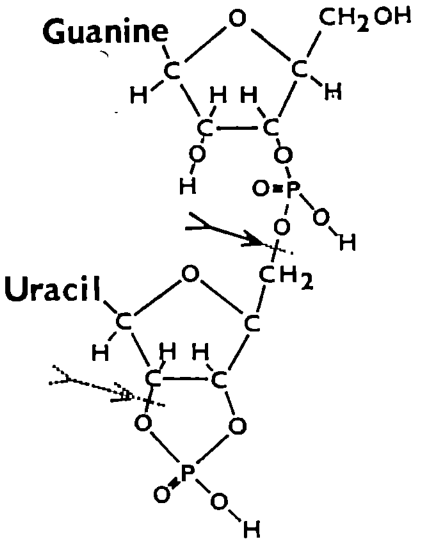

Fig. 2. Probable structure of the guanine–uracil dinucleotide anhydride. The arrows show the alkali labile bonds, while the dotted arrow indicates the bond which is also broken by ribonuclease

Now these properties parallel exactly the behaviour of the pyrimidine nucleotide 2′, 3′ anhydrides, so it would seem that the dinucleotides of bands 3 and 5 contain the latter joined at position 5′ as one half of the molecule.

The purine nucleotides derived from these dinucleotides by alkaline hydrolysis are of the 2′ and 3′ types and the dinucleotides do not react with periodate, so that the internucleotide link must be of the 3′ (or 2′), 5′ type. The only likely formula for the guanine–uracil dinucleotide anhydride is given in Fig. 2 (it being understood that at the moment it is not possible to distinguish between a 2′ and a 3′ nucleotide residue in such a compound, as hydrolysis invariably results in the formation of roughly equal amounts of the 2′ and 3′ nucleotides).

Discussion

It will be seen from these results that a large number of the internucleotide linkages in yeast ribonucleic acid are of the 3′ (or 2′), 5′ type and also that some at least of the alkali labile bonds of ribonucleic acid are situated at the 5′ sugar carbon atoms. From this it would appear that the linkages broken by ribonuclease are similar to those broken by alkali, with the important exception that ribonuclease distinguishes between purine and pyrimidine nucleotides. We have found that, by cautious alkaline hydrolysis of ribonucleic acids, using barium carbonate at 100°, corresponding to a pH of just over 9, the anhydrides of the pyrimidine nucleotides are released, showing the analogy of the action of alkali and ribonuclease.

The general nature of the products of ribonuclease digestion suggests that, as in alkaline hydrolysis, it is necessary for a cyclic intermediate to exist, and that this intermediate must also be a pyrimidine nucleotide derivative. This would explain the rapid formation of the large amounts of the anhydrides *C* and *U*, as they would be chopped out of the ribonucleic acid wherever two or more adjacent pyrimidine nucleotides having either a free 2′ or 3′ —OH group were to be found in the molecule. The existence in the digests of the free 2′- and 3′-guanylic and adenylic acids is difficult to account for by this theory, unless they were joined to pyrimidine nucleotides by a 2′, 3′ link (or the equivalent), as this link would allow the formation of the intermediate anhydride.

A study of the trinucleotides of band 1 and the larger products of ribonuclease digestion is now being made in an attempt to confirm this theory, and we are also hoping to be able to make quantitative estimates of the amount of the various constituents on the well-characterized and undegraded turnip yellow mosaic virus nucleic acid[4].

It is a pleasure to thank Prof. D. Keilin and Dr. K. M. Smith for their interest in this work. We are also greatly indebted to Prof. A. R. Todd and his colleagues, notably Drs. Brown and Dekker, for discussing problems of mutual interest.

OBITUARIES

Prof. A. J. Allmand, F.R.S.

Prof. A. J. Allmand, emeritus professor of chemistry in the University of London, died in hospital in London on August 11 after an operation.

He was the son of Frank Allmand and was born at Wrexham in 1885. He was educated at Alleyn's School, Dulwich, at Grove Park School, Wrexham, and at the University of Liverpool. He also studied at the technical high schools of Karlsruhe and Dresden. He took his D.Sc. in Liverpool in 1910 and then returned to study in Germany as a Science Research Scholar of the Exhibition of 1851. At Karlsruhe he worked under Prof. F. Haber on the measurement of radiation from flames, and at Dresden he worked under Prof. Luther on the primary products of photochemical change. He then took the post of assistant lecturer and demonstrator at Liverpool, where he was one of the group of chemists inspired by Donnan, whom he always regarded with gratitude and affection. At this period his work was naturally concerned with electrochemistry, and in 1912 he published his well-known text-book on the "Principles of Applied Electrochemistry", of which a revised edition was published in 1925.

During the First World War, Allmand was called upon to bring his knowledge and experience to bear upon the new problems of chemical warfare. He became chemical adviser to the Fourth, and later to the Second, Army H.Q., with the rank of major, and during this period he was awarded the Military Cross. His Army service left him with an enduring enthusiasm for military life and history which is somewhat unusual among men of science, and in his library the official history of the war jostled with the *Proceedings* (*A*) *of the Royal Society*, and was studied with equal diligence and zest.

In 1919 Allmand was appointed professor of chemistry at King's College, London, where he spent the remainder of his academic life until his retirement in 1950. While maintaining his interest in electrochemistry and developing the Drumm transport battery, he worked mainly in two other fields, namely, in the adsorption of gases and vapours by charcoal, and in photochemistry. In the latter field he was specially interested in photolysis and the photochemical reaction between hydrogen and chlorine. In both these fields he carried out a large amount of accurate experimental work which played an important part in future developments.

In 1938 he succeeded Prof. S. Smiles as Daniell professor and head of the Department of Chemistry at King's College. He was a member of the Senate of the University of London from 1929 until 1932, and he acted as assistant principal of King's College during 1937–43. He was elected a Fellow of the Royal Society in 1929 and made a Fellow of King's College in 1932.

During the Second World War, Allmand was again called to serve his country, this time as superintendent of the Explosives Research Department in the Ministry of Supply—an exacting task which he combined with almost nightly fire-watching duties at King's College. After the War his research interests returned again to electrochemistry, and his most recent publication dealt with the simultaneous electrodeposition of zinc and copper from solution. It was fitting that his last official position was that of president of the Faraday Society, a post which he held during 1947–48.

Although Allmand was a great teacher and a very distinguished physical chemist, it is more by his extraordinary personal influence that he will be remembered rather than by his purely scientific contributions. He was one of the most loved and revered members of the Common Room at King's College. His Department was singularly happy and harmonious. He was always greatly interested in the work and welfare of all his students, both while they were at College and afterwards when they occupied posts in universities or industry. They in turn regarded him with warm affection, and, at his farewell dinner, every year since his appointment was represented by a group of former students.

He was a man of complete moral integrity, whose whole life was inspired by spiritual purposes. His advice and judgment were always sound, selfless and rigidly based on principle. He was severe and ascetic with himself, although never censorious of others. On the rare occasions when he expressed disapproval, he was decisive and final; but he will be remembered more readily for the warm encouragement of his approval and the frequent generosity of his help. He was one of the most modest and self-effacing men in the College; but he has left a deep and enduring influence and a noble example.

He leaves a wife, a son and a daughter. His elder son, Michael, was wounded in the Burma campaign and was posthumously awarded the Victoria Cross for great gallantry in action. G. Temple

Prof. Hantaro Nagaoka

Prof. Nagaoka was born on August 18, 1865, when Japan was in the midst of turmoil centring on the problem of the re-opening of trade and diplomatic relations with European countries and the United States after two hundred years of isolation from the rest of the world. He graduated from the College of Science of Tokyo Imperial University (now the University of Tokyo) in 1887, not long after it had been established by the new government. He obtained his doctorate in 1893 and, after having studied further in Germany for three years, he was appointed professor of physics at Tokyo Imperial University and held that position from 1896 until 1926. From 1926, he continued to carry out research at the Institute of Physical and Chemical Research (now Scientific Research Institute) in Tokyo until 1945. Even after he left the Institute, he was actively engaged in research work up to the very end of his life, which came on December 10, 1950, at the age of eighty-five.

Prof. Nagaoka published more than three hundred scientific papers covering a wide range of pure and applied physics, extending from hyperfine structure of atomic spectra to the theory of earthquakes. His earliest work on geophysics was followed by the investigation of magnetism, which was further extended by K. Honda. Then his interest turned to spectroscopy. In his latest years, he returned to various subjects on geophysics. Among numerous papers, however, he is best known by his pioneering work on the atom model, which appeared in the *Philosophical Magazine* in 1904. His Saturn model of the atom could be regarded, in a sense, as the forerunner of the Rutherford–Bohr theory. It is also worth while mentioning that he predicted the existence of the ionosphere quite independently of Kennelly and Heaviside.

Prof. Nagaoka was elected a member of the Imperial Academy of Japan (now the Japan Academy) in 1905 and was president of the Academy during 1939–48. He was the first president of Osaka (Imperial) University, which was established in 1931. He was elected an honorary member of the Physical Society of Japan in 1950 and was among the first who received in 1937 the Order of Cultural Merit, a medal of high distinction. Honours came also from abroad. He was elected an honorary fellow of the Physical Society of London in 1912, and received in 1925 the honorary degree of doctor of philosophy from the University of Cambridge.

His influence, both direct and indirect, was great on a large number of younger Japanese, who looked up to him as an outstanding native scientist, as they were eager to catch up with Western science and technology. He was a born scientist with a genuine love of Nature. His tireless endeavour for nearly sixty years in search of truth justly earned his reputation.

Hideki Yukawa

Dr. C. D. Perrine

We record with regret the death, which occurred on June 21, 1951, at the age of eighty-three years, of Dr. Charles D. Perrine, former director of the Cordoba Observatory, Argentine. Dr. Perrine began his astronomical career at the Lick Observatory in 1893. He made many observations of comets, and was active in discovering them, his discoveries including comets 1895 IV, 1896 I, 1896 VII (periodic), 1897 I, 1897 III, 1898 I, 1898 VI, 1898 IX, 1902 III. He was also the first to observe the periodic comets, D'Arrest at its return in 1897, Pons-Winnecke at its return in 1898, and Temple (2) at its return in 1899. In 1904 he discovered, on photographs with the Crossley reflector, the sixth satellite of Jupiter, and the following year the fainter seventh satellite; these two satellites form a pair with nearly the same mean distances (about seven times greater than that of the most distant of the previously known satellites) and have interlocking orbits. Their motions are subject to large perturbations. From observations with the Crossley reflector of Nova Persei 1901, Perrine discovered the expanding nebulosity around the nova, caused by the light from the outburst as it travelled outwards, illuminating the interstellar cloud in which the nova happened to be. From his observations of faint spiral nebulæ he was able to conclude that the number of such systems discoverable with this telescope was about half a million, providing the first evidence of the vast number of these objects, which has been fully confirmed by later observations. In 1903 he succeeded in obtaining the spectrum of Nova Aurigæ (1891) which was then of the 14th magnitude, and showed that it consisted of bright lines superposed on a continuous spectrum.

In 1909 Perrine left the Lick Observatory to take up the appointment of director of the Cordoba Observatory, a position which he held until his retirement in 1936. A fine series of photographs of Halley's Comet at its return in 1910, together with measurements of position and of brightness, were obtained, which formed the basis of a large volume, published in 1934, which contained excellent reproductions of many of the photographs, together with the observations and their discussion. Sixteen volumes of the "Resultados del Observatorio Nacional Argentino" were published under his direction. By his energy and enterprise, Perrine was responsible for the creation of the Astrophysical Station at Bosque Alegre, with its 60-in. reflector.

Perrine was interested in eclipse observations. He led the Lick expedition to Sumatra in 1901 to observe the total eclipse of May 18 that year, which secured successful observations. In 1914 he joined with Dr. W. W. Campbell, director of the Lick Observatory, in an expedition to the Crimea to observe the eclipse of August 21. Observations were hindered by clouds and the return journey was complicated by the outbreak of the First World War.

Perrine was awarded the Lalande prize of the Paris Academy of Sciences in 1897. In 1902 he was president of the Astronomical Society of the Pacific. He was elected an Associate of the Royal Astronomical Society in 1904, and at the time of his death was the senior, by nine years, of the Associates of the Society.

H. Spencer Jones

We regret to announce the following deaths:

Prof. Gilbert Cook, F.R.S., emeritus professor of civil engineering and mechanics in the University of Glasgow, on August 28.

Prof. T. H. Johnston, professor of zoology in the University of Adelaide, known for his work on the control of prickly pear in Australia, on August 30, aged sixty-nine.

Prof. G. Steindorf, formerly professor of Egyptology in the University of Leipzig, on August 28, aged eighty-nine.

NEWS and VIEWS

Sir Arthur Schuster (1851–1934)

SIR ARTHUR SCHUSTER, who was born in Frankfurt-on-Main a century ago, on September 12, entered his father's business at Manchester in 1870. After studying physics and mathematics at Owens College, he took up spectrum analysis and went to work with Kirchhoff at Heidelberg, where he obtained his Ph.D. degree in 1873. Further study at Göttingen and Berlin was followed by his leadership, when only twenty-four, of the Royal Society's solar eclipse expedition to Siam. Subsequent expeditions took him to Colorado, Egypt and the West Indies. He became a naturalized British subject in 1875. After five years under Clerk Maxwell and Lord Rayleigh at the Cavendish Laboratory, Cambridge, he was appointed professor of applied mathematics at Owens College in 1881, succeeding his former teacher, Balfour Stewart, as Langworthy professor of physics in 1888. He was elected a Fellow of the Royal Society at the age of twenty-eight. He was secretary of the Royal Society during 1912–19, foreign secretary during 1920–24, and vice-president 1919–24; he received a Royal and the Rumford and Copley Medals. Schuster carried out important work on the discharge of electricity through gases, in meteorology, in terrestrial magnetism, and on the mathematical theory of periodicity; he was the first to photograph the spectrum of the solar corona. His classic "An Introduction to the Theory of Optics" was published in 1904. He was president of the British Association for the Manchester meeting in 1915, and was knighted in 1920. After his retirement from the chair at Manchester, he took an active part in fostering international collaboration in science, and was the first secretary of the International Research Council, which in 1931 became the International Council of Scientific Unions. Reserved and difficult to know, Schuster was always the friend of his students. He died on October 14, 1934.

National Physical Laboratory: Fifty Years of Progress

ON January 1, 1900, Sir (then Mr.) Richard Glazebrook was appointed the first director of the National Physical Laboratory at Teddington; and although Bushy House, once a Royal residence, was not formally opened as the Laboratory proper until March 19, 1902, the Laboratory can be said to date from Glazebrook's appointment. Thus to celebrate the jubilee, an exhibition of the work of the Laboratory was held in the Royal Society's rooms on January 30, 1950 (see *Nature*, 165, 257; 1950), and during May 23–29 this year the 'open days' of the Laboratory were intended partly as a jubilee celebration (see *Nature*, June 23, p. 1006). Bushy House with its gardens is still part, but now only a corner, of the fifty-acre estate on which sixteen major and minor buildings have been constructed to house the ever-growing needs of the Laboratory. The history of the growth and development of the Laboratory and the story of its many activities is of interest, not only to men of science all over the world, but also makes fascinating reading for the less technically minded public. The publication, therefore, of the Jubilee Book of the National Physical Laboratory (pp. 104+32 plates; London: H.M. Stationery Office, 1951; 4*s*. net) in time for the many visitors both from home and overseas in London for the Festival was greatly to be welcomed. Written by John Langdon-Davies and profusely and beautifully illustrated, it gives an accurate, interesting and easily read description of the way in which, in spite of difficulties and the increasing number of new branches of applied science, the Laboratory still gives pride of place to the science and art of measurement. The book consists of seven chapters, beginning with a discussion of the importance of accuracy in all the work at Teddington. Chapter 2 describes the origin of the Laboratory and chapter 3 its organization and relation to other bodies. The two succeeding chapters outline the maintenance of standards and the type of research that is undertaken, and the final two discuss some recent investigations and special types of research. There can be no doubt that the Laboratory will continue, as in the past, to be the champion of accuracy in measurement; an invaluable storehouse of equipment, techniques and personnel which could not be spared without serious loss to the nation's scientific capital; and an effective instrument for making existing scientific knowledge known as rapidly as possible to industry and others who are in a position to use it.

Research Council of Alberta

THE thirty-first annual report of the Research Council of Alberta covering the year 1950, like earlier reports, stresses the importance of the investigations of the Athabasca bituminous sands, both as road material and as a source of liquid fuel. Co-operative experiments in the National Research Laboratories have demonstrated the feasibility of combining the hot-water separation process with the fluidized-bed cracking and distillation process, using the wet crude oil from the former as feed stock for the latter process; and by use of this combination the economic development of the bituminous sand is reported as immediately practicable. Besides further work on the cleaning, briquetting and balling of coal, studies on the constitution of coal have been made, including an investigation of the oxidation of low-rank Alberta coals. A preliminary survey was made of the Pleistocene deposits of the Edmonton area and a survey of automobile lubricating oils for sale within the Province was continued, as well as various other investigations of petroleum and associated products, including a study of anti-freeze solutions. Work continued on compaction studies on new road construction, and as a result of preliminary investigations on the causes of cracks in asphalt paving that do not appear to be associated with overloading of the road structure, consisting of pavement-supporting base and sub-soil, a detailed programme has been planned for the winter period. Two locations of unstable hillsides have been studied in detail to assess the soil conditions accompanying such instability.

The natural gas research programme comprises three current projects: the catalytic pyrolysis of natural gas in a fluidized bed; the kinetics and yields of the partial oxidation of butane in the gas phase; and an evaluation on the pilot plant of the National Research Council's process for carbon black from natural gas. An irrigation survey of the Bow River was completed as well as one of the Carmangay, and a preliminary survey of the William Pearce project for diverting some of the water of the Red Deer River. Some 400,000 acres were mapped in the Brazeau–Rocky Mountains House area, and about 1,750,000 acres in the McLennan and High Prairie area. Exploratory surveys were made of an area north and west of Blueberry Mountain and of an area north of Hotchkiss. Accumulation of records of ultra-violet solar radiation with the thorium photocell continued, and a study is being made of the relative response at different wave-lengths of the three photo-cells used in the investigation. Problems of biological cycles, particularly the alternate prevalence and scarcity of forms of wild life, are being examined, including both the rabbit cycle and the collection of grouse material. A list of publications of the Research Council is appended.

National Foundation for Scientific Research, Brussels : Annual Report for 1949–50

The twenty-third annual report of the National Foundation for Scientific Research, Brussels (pp. 196 ; 1950), covers the year 1949–50, and, besides lists of publications and of members of the scientific commissions, includes notes on the work in progress at Brussels, Ghent, Liège, Louvain, Mons and the Royal Military School. This has included studies on the following topics : the separation of isotopes by thermodiffusion in the liquid phase, the properties of uranium salts, the metallurgy of nuclear pure uranium, the preparation of pure graphite, heavy water, geological applications of radioactivity, neutrons, thick photographic emulsions, the preparation of uranium fluoride and hexafluoride, the variation of intensity of a pencil of neutrons with distance in terms of the medium interposed, the absorption of neutrons and the technique of the photographic plate. In addition, there have been some biochemical investigations, and studies in mass spectrography, the separation of isotopes, slow neutrons and nuclear isomerism, and the construction of a high-tension cathodic oscillograph and a linear accelerator of protons. In the financial statement, besides research grants totalling 3,125,000 francs for the year, the National Foundation has approved a supplementary grant of 2,000,000 francs for a Franco-Belgian expedition for submarine exploration, and 'extraordinary grants' of 212,971 francs to the University of Liège for the acquisition of a camera for cinematographic registration of rapid physical phenomena. Other grants are : 250,000 francs for the construction of an apparatus for X-ray emission and absorption spectra ; 100,000 francs to the University of Liège for transporting and installing at the scientific station of the Jungfraujoch the cœlostat and large infra-red spectrometer from Cointe Observatory ; 175,000 francs for sociographical research at the University of Brussels ; 250,000 francs to the University of Louvain for a campaign of excavation at Alba Fucens ; and 250,000 francs for equipping the four universities for biological research with radioisotopes. Besides a full list of publications by recipients of grants during the year 1949–50, there is appended a list of recipients of grants for 1950–51 and of their research objectives.

American Institute of Physics : Twentieth Anniversary

The twentieth anniversary of the American Institute of Physics will be celebrated in Chicago during October 23–27 by a joint meeting of the founding societies of the Institute. Member societies which will hold their regular autumn technical meetings during the five-day anniversary celebration are the American Physical Society (October 25–27), Optical Society of America (October 23–25), Acoustical Society of America (October 23–25), Society of Rheology (October 24–26), and the American Association of Physics Teachers (October 25–27). The American Crystallographic Association, an affiliated society of the American Institute of Physics, will also participate in the anniversary meeting. An all-day symposium on October 25, on the theme "Physics To-day", will include papers by Dr. Enrico Fermi, University of Chicago ; Dr. E. U. Condon, retiring director of the Bureau of Standards ; Prof. J. C. Slater, Massachusetts Institute of Technology ; Dr. Harvey Fletcher, Columbia University ; and Dr. Edwin H. Land, president and director of research of the Polaroid Corporation. The symposium will be concluded with a more general talk entitled "Physics as Science and as Art" by Dr. K. K. Darrow, of the Bell Telephone Laboratories. Senator Brien McMahon, chairman of the Joint Congressional Committee on Atomic Energy, and Dr. K. T. Compton, chairman of the Corporation of the Massachusetts Institute of Technology, will be guest speakers at a joint banquet on October 25. Included in the programme will be an industrial exhibit of scientific instruments and apparatus arranged by the leading manufacturers of scientific equipment in the United States. Further information can be obtained from the Secretary, American Institute of Physics, 57 East 55th Street, New York City.

New Indian Institute of Technology

A new Institute of Technology, the first of four such institutes which it is hoped to build in India, is in the course of being constructed at Kharagpur, seventy-two miles from Calcutta, and already more than two hundred students are attending courses in buildings already in existence on the site. It is expected that the Institute will be finally completed and equipped in about four years time, and then it will be able to take about two thousand students. Mr. Jerzy Malanowski, a mechanical engineer, has recently gone to the Institute as the first member of a team from the United Nations Educational, Scientific and Cultural Organization under the United Nations Technical Assistance plan. Mr. Malanowski's work, besides organizing the four-year course in mechanical engineering and lecturing to students, will be to help plan and construct laboratories and workshops and their equipment for the Institute. Courses will be run on similar lines to those at the Massachusetts Institute of Technology. Departments of civil and sanitary engineering, electrical engineering, mechanical engineering, building construction and architecture, metallurgy, naval architecture and marine engineering, and geology and geophysics are being set up, and students will follow a four-year course leading to the degree of B.Sc. Eventually postgraduate courses, lasting a year, will be organized.

Measurement of Low Temperatures

Since the end of the Second World War interest in the field of low-temperature physics has expanded considerably, and there are now many more physical laboratories either engaged on, or about to embark on, low-temperature research work. Though the methods of measurement of temperatures below 90° K. are well established and are fully described in the literature, it would be difficult to find, if such exists, a comprehensive statement of them in any one book or periodical. The handy reference monograph on "The Measurement of Low Temperatures" (Research Report R-94433-2-A ; Physics Department, Westinghouse Research Laboratories, East Pittsburgh, Penn. ;

free) which C. T. Linder has compiled is therefore timely and should prove most useful. The contents of the monograph consist of details of the different methods of temperature determination, together with tables and graphs of data useful in the practical application of those methods. First, the low-temperature scale is briefly outlined, and then in more detail the gas and vapour thermometers, the thermocouple and the resistance thermometer are discussed. Finally, the measurement of temperatures below 1° K. is briefly considered, and the suggestion of Lawson and Long to use the Brownian motion, though not yet experimentally verified, is mentioned. The tables and graphs constitute nearly two-thirds of the monograph, and although the complete monograph is a photographic reproduction of typescript, the tables and graphs are exceptionally clear and easy to read. Every effort has been taken to make the material presented as up-to-date as possible. Table 2, consisting of seven pages, deals with the variation with temperature of the vapour pressure of helium and has been copied directly from material, dated June 1949, made available by the Royal Society Mond Laboratory, Cambridge.

Astronomical Photographs from the Yerkes Observatory

SINCE 1903 the Yerkes Observatory of the University of Chicago has been reproducing, in lantern slides, transparencies and prints, the original astronomical photographs made at Williams Bay. Within recent years, copies of photographs made at other observatories have been added to the collection, and these reproductions are sold by the University of Chicago Press. In "Astronomical Photographs", an illustrated catalogue edited by Thornton Page (pp. 36; Williams Bay, Wis.: Yerkes Observatory, 1951), the reproductions are listed and can be ordered by catalogue number from the Photographic Service Department, Yerkes Observatory, Williams Bay, Wisconsin. One hundred 3¼ in. × 4 in. slides for the use of teachers and lecturers are available, and at greatly reduced cost sixty selected slides are now offered in the 2 in. × 2 in. size, and on 35 mm. film strip, the former at 25 dollars for the sixty and the latter at 10 cents each. In addition to the set of selected slides for general use, the catalogue lists and describes slides and photographs illustrating specific research problems of modern astronomy and astrophysics—problems of the solar chromosphere and corona, of planetary atmospheres, of the origin of the solar system, of the aurora borealis, of lunar craters, of meteor and comet spectra, of interstellar clouds, of novæ and supernovæ, of the spectra of all types of nebulæ, and of galactic structure. The list finishes off with maps of neon and iron spectra, views of modern and historical instruments, and portraits of ninety famous astronomers.

Petroleum Consumption and Production in Great Britain

THE Petroleum Information Bureau has recently issued a pamphlet (pp. 8; London: 29 New Bond Street, W.1; 1951), at the behest of the U.K. Petroleum Industry Advisory Committee, setting forth statistics on consumption of petroleum products; deliveries of motor spirit to dealers and commercial consumers; analysis of deliveries into consumption of gas, diesel and fuel oils; production of petroleum products from imported and indigenous crude and process oils; and indigenous materials made available for distribution by the petroleum industry. From the statistics given it appears that, during 1950, 5,195,173 tons of motor spirit, including motor benzole, were consumed in Great Britain. Considering that petrol rationing was not lifted until May 1950, this is a high figure, one, however, certain to be greatly exceeded for the current year. Total deliveries of gas, diesel and fuel oils for burning and power in the same year amounted to 5,337,791 tons. During the year Great Britain produced 949 tons of indigenous petrol by low-temperature carbonization, 130,177 tons of petrol and aviation spirit by hydrogenation and 188,842 tons of refined benzole—not an unworthy record.

Cambial Injuries in a Pruned Stand of Norway Spruce

A FORESTRY Commission publication, Forest Record No. 4 (pp. 12; London: H.M. Stationery Office, 1950; 9*d*. net), by W. R. Day, is devoted to "Cambial Injuries in a Pruned Stand of Norway Spruce" and is based on an experiment made of pruning the side branches of Norway spruce with the object of raising the quality of timber and so the economic value of the crop. One of the pruning experiments was carried out in Drummond Hill Forest on Loch Tay-side, Perthshire, at four different times of the year—May, July, October and January. Unpruned control plots were maintained, and all the plots had been brashed up to a height of about 6 ft. The trees in the forest were planted in 1912 and were thirty-five years old when examined in 1947. In a summary of the research work undertaken, the author says that a severe case of bark necrosis occurred, owing to frost damage, usually after the pruning had taken place and either at the beginning or end of the growing season. The damage to the unpruned trees was much less severe. The wood made by the spruce is abnormal in that its cell walls are of a weak structure and tend to be insufficiently lignified, especially the late wood. A typical feature of these trees is that the annual ring ends abnormally, indicating that their growing season is unduly long considering the type of climate in which they grow. The experimental demonstration of the diagnosis put forward in this paper is under consideration. The technical difficulties are involved, and research will be required into the relationship between provenance of spruce seed, that is, of the variability of a species and the relative usefulness of its variations in any particular region. Research is also required in the type of wood developed in Great Britain and susceptibility to the type of injury here described—a matter of some importance, for the results might seriously affect the productive efficiency of future plantations.

Chestnut Blight

THE symptoms of chestnut blight, caused by the fungus *Endothia parasitica*, are described and illustrated in colour in Booklet No. 3 of the Forestry Commission (pp. 4+4 pl.; London: H.M. Stationery Office; 1950; 2*s*. 6*d*. net). This is a disease of the sweet chestnut, *Castanea sativa*, which has not yet been found in Great Britain; it has, however, caused very serious damage in the United States and is established in Italy and Spain. There is sufficient sweet chestnut in France to form a potential infection-bridge to the fairly extensive coppices of this tree in the south of England, and it is therefore highly desirable to recognize any possible occurrence in

Britain and to limit its spread, if discovered. The fungus attacks the bark, girdles the tree with a typical canker and kills the part beyond the canker. Orange-yellow spore tendrils are produced in moist weather, and the fungus also produces mycelial fans under the bark. Chestnut blight can be distinguished from ink disease of the same tree in that the latter kills the tree completely, whereas the former often allows normal growth in the part below the canker. The Forestry Commission invites reports of suspected cases of the disease to its Research Station, Alice Holt Lodge, Farnham, Surrey. It is pointed out that material should be packed in a tin to avoid spreading fungus spores during transit.

Animals of Scotland

To accompany a new section devoted to animals of Scotland in the "Habitat Court" of the Glasgow Art Gallery and Museum, a suitable booklet has been prepared by the curator of the natural history department. This describes the appearance and habits of the twenty-eight mammals and birds included in the exhibit as well as their general taxonomic characters. Other exhibits are concerned with the animals of Africa, India and Australia, and the number of visitors they are attracting indicate their popularity. A fifth exhibit, featuring animals of arctic and antarctic regions, is under construction.

Fear and Social Structure

According to Dr. Grantly Dick Read, the influence of fear on social structure is not well understood or appreciated (*South Afr. J. Sci.*, 47, No. 8; March 1951). Practically the whole basis of human communal existence to-day, he suggests, is influenced by fear; man's mental and physical health vary as to his ability to remain balanced in face of fear. Dr. Dick Read also suggests that children are not only emotionally influenced from the moment of their birth but even from the moment of conception. At fifteen weeks the reflexes of the fœtus indicate individuality of behaviour. From birth the child is regularly subjected to stimuli which induce fear and lead to insecurity. According to its nature the child risks rebellion in violence or excessively anti-social behaviour, or resolves into that submissive state when even attempted activity of any sort, or any expression of its individuality, is paralysed by the deeply implanted fear of consequences. Dr. Dick Read believes that much of this unnecessary fear with its harmful effects on the individual and society would be eliminated if the fear of child-birth in women were eliminated.

Montefiore Prizes for Electrical Development

Montefiore Prizes, awarded by the George Montefiore Foundation of Liège, have been awarded to Dr. U. Krabbe (Fruens-Bøge, Denmark), for an essay on "The Transductor Amplifier"; Dr. M. Hoyaux (Charleroi), for an essay on "Théorie de la chute dans l'arc des redresseurs à vapeur de mercure"; E. H. Hubert (Liège), for an essay on "Contribution théorique et expérimentale aux possibilités d'application du réenclenchement automatique des disjoncteurs"; and R. Pellisier (Paris), for an essay on "La propagation des ondes transitoires et périodiques le long des lignes électriques". These Prizes are usually given every five years; but the present awards are for the period 1939–50. They were established by a bequest of M. Montefiore, who founded the Electro-Technical Institute of the University of Liège, and are given for original contributions of scientific or technical significance for electrical progress. The committee of award consists of five Belgian and five non-Belgian engineers. Seventeen essays were submitted on this occasion. Particulars relating to the awards can be obtained from the Fondation George Montefiore, Université, Liège; the next awards will be made in 1955.

Unification of the "Air Almanac" and the "American Air Almanac"

As from 1953, the "Air Almanac" and the "American Air Almanac" will become a single publication, under the title of the "Air Almanac". It will be produced jointly by H.M. Nautical Almanac Office of the Royal Greenwich Observatory, Herstmonceux, and the Nautical Almanac Office of the U.S. Naval Observatory in Washington, to meet the general requirements for air navigation in the United Kingdom, the United States and Canada. The "Air Almanac" will be printed and published separately in England and the United States, but will otherwise be identical. A number of changes have been necessary in both the former publications. None of these has any effect on the principles of tabulation or on the use of the "Almanac" in navigation.

British Institution of Radio Engineers: Premiums for 1950

The British Institution of Radio Engineers has awarded the following Premiums for 1950, the awards being based on papers (titles as indicated) published during the year in the *Journal* of the Institution: *Clerk Maxwell Premium* (for the most outstanding paper of the year), to D. W. Heightman, English Electric Co., Ltd. (propagation of metric waves beyond the optical range); *Heinrich Hertz Premium*, R. Kompfner, Clarendon Laboratory, Oxford (operation of the travelling-wave tube at low level); *Louis Sterling Premium*, J. E. B. Jacob, Cinema Television, Ltd. (high-performance television monitors); *Dr. Norman Partridge Memorial Award*, S. W. Punnett, University College, Southampton (audio frequency selective amplifiers).

Announcements

Prof. Emile Guyénot, *correspondant* for the Section of Anatomy and Zoology of the Paris Academy of Sciences and professor of zoology and comparative anatomy in the University of Geneva, has been elected a non-resident member of the Academy in succession to the late Prof. L. Cuénot, formerly professor of zoology in the University of Nancy.

Prof. G. L. Brown, Jodrell professor of physiology in the University of London, and Sir James Learmonth, regius professor of clinical surgery and professor of surgery in the University of Edinburgh and surgeon to H.M. The King, have been appointed members of the Medical Research Council as from October 1.

The annual 'open day' at the Chemical Research Laboratory (Department of Scientific and Industrial Research), Teddington, will be on September 19.

The Medical Research Council announces that travelling awards in ophthalmology and otology under the Alexander Pigott Wernher Memorial Trust, tenable during the academic year 1951–52, have been made to Dr. Patricia R. Davey (Sydney) and Dr. R. N. Misra (Medical College, Lucknow).

ÇHEMISTRY AND TECHNOLOGY OF METALS AND ALLOYS

THE joint meeting of the Sections B (Chemistry) and G (Engineering) of the British Association, held on August 14 at Edinburgh to discuss "Metals and Alloys", was noteworthy because it was the first time in the history of the Association that a meeting had been devoted exclusively to subjects of metallurgical interest. This was pointed out in his opening remarks by the chairman, Sir Andrew McCance, who went on to remind his listeners that announcements of historic metallurgical importance have nevertheless been made at earlier meetings; for example, at the Cheltenham meeting in 1856 Bessemer made the first public announcement of his revolutionary process for making steel from pig iron without fuel by blowing air through it. Sir Andrew aptly summed up the course of metallurgy during the past hundred years by saying that the latter half of the nineteenth century was devoted to developing the art of manufacture on an ever-increasing scale, whereas the first half of this century has been characterized by an equally intense endeavour to understand the scientific principles of the processes in use.

This was well illustrated by the paper on "Chemistry in Metal Extraction" given by Dr. F. D. Richardson. The study of the physical chemistry of metals and slags is a development of the past twenty-five years; and so far as the older metal industries are concerned, research has been aimed at establishing the physico-chemical background of existing processes, and no startling discoveries have been made. On the other hand, chemical research has been directly responsible for the methods of extracting such new and costly metals as titanium, zirconium and uranium. Concerning metal extraction at high temperatures, least is known about molten slags and mattes, and research is therefore required on the chemistry of molten silicates, oxides and sulphides and their mixtures. According to the picture so far developed, molten silicates consist of disordered three-dimensional networks of tetrahedral silicate groups (SiO_4). These groups share corners with one another via Si—O—Si 'bridges' which can be broken by the addition of metal oxides, with a corresponding decrease in viscosity. When all the bridges have been broken, addition of further metal oxide gives rise to oxygen and metal ions dispersed between silicate tetrahedra. Much confusion has arisen from theories of the formation of various kinds of molecular compounds in liquid slags; but Dr. Richardson stressed that the only entities that can be recognized as having a distinctive existence are the metal ions, the silicate tetrahedra (which carry a net negative charge and may be bridged together in varying degrees) and the excess oxygen ions.

The rates of reactions between slags and metals are not controlled by the chemistry of the processes which take place at the interface between them but by the diffusion of reactants and resultants to and from the interface, particularly in the slag, since diffusion in the slag is generally much slower than in the metal. The rates of refining processes with slags can also be increased by efficient mixing of the slag and metal. The partition of sulphur between slag and metal obtained in the blast furnace is much less favourable than can be obtained under equilibrium conditions in the laboratory, and Dr. Richardson suggested that pig iron of lower sulphur content might be made by mixing slag and metal in the ladle after tapping. This would be an additional operation; but the slag and metal would be readily available at the desired temperature. It might also be practicable to recover the sulphur from the enriched slag by blowing air or oxygen through it, and to use the sulphur dioxide evolved for manufacturing sulphuric acid. If so, the seven million tons of blast-furnace slag made annually in Britain would be a potential source of a hundred thousand tons of sulphur.

The second paper, by Prof. A. H. Cottrell, was concerned with "The Strength of Metals". The atoms in a slip plane cannot all slip simultaneously over their neighbours in the next plane; slip must begin at certain places and then spread. The term 'slip dislocation' is applied to the line boundary separating the region in which slip has occurred from the rest of the slip plane. Three important properties of a slip dislocation are: when a slip dislocation is moved in a slip plane the amount of plastic deformation in the crystal is altered; the stress needed to move a dislocation through a slip plane of an otherwise perfect crystal is smaller than the smallest observed yield-strength; and third, the stress needed to create a dislocation in a perfect lattice is larger than the highest observed strength. This last property implies that slip dislocations must be present in crystals before they are plastically deformed. Support for this idea has been provided by Frank's theory of crystal growth, according to which growth occurs by deposition along spiral terraces on crystal faces, the centre of each spiral being the point where a dislocation line emerges from the interior of the crystal. On this theory the imperfect crystals, that is, the ones containing dislocations, are those most likely to grow. Growth spirals have been observed on both inorganic and organic crystals.

Prof. Cottrell then showed how dislocation theory explains the effect on the yield-strength exerted by foreign atoms, precipitates, crystal boundaries and other irregularities which are obstacles to the propagation of dislocations. Strain-hardening—one of the first problems to be studied from the point of view of dislocations—is the outstanding unsolved problem facing the theory. According to recent work the initial dislocations tend to assemble in sheet-like arrays that are very stable and act as barriers to the propagation of later dislocations; these special arrays of dislocations appear to be the main cause of strain-hardening; but it is not yet known why they are formed in the first place and why they are so stable.

A survey of alloy development during the past ten years or so was given by Prof. A. G. Quarrell. To a large extent new alloys are developed to meet the needs of the engineer, and the gas turbine has provided an incentive for the development of alloys with improved high-temperature properties in much the same way that the needs of the aircraft industry led to the introduction of alloys of better strength-to-weight ratio. For the most part the improvement of alloys is still empirical, depending upon the 'metal sense' of the metallurgist, and most of the alloys now technically important are complex, containing from six to ten alloying elements. It is to be hoped that, as the theory of alloy formation becomes more complete, it will be possible to design alloys on a more rational basis and possibly with greater economy of alloys.

After reviewing some of the characteristics of "Brittle Fracture in Mild Steel", which has become so important since the introduction of welding on a large scale into shipbuilding, Mr. T. S. Robertson went on to describe a new form of test for the assessment of brittleness. In this test a shock crack propagated at low temperature passes through material stressed to a value comparable with that carried by the structure in practice. A temperature gradient is maintained along the direction followed by the crack, and this enables the temperature at which the material arrests propagation of the crack to be determined. As the transverse stress is reduced there is a sudden drop in the temperature at which the propagating crack is arrested, and Mr. Robertson suggested that this stress could be regarded as a safe design stress below which there is no chance of brittle fracture at ordinary working temperatures. Mr. Robertson illustrated his remarks with an excellent colour film of a test in progress. This showed that the speed of crack propagation is such that for the usual travel of about six inches, photography at 4,000 frames per second is too slow to record it, since no film so far taken has shown the crack in process of development. The speed of propagation must therefore exceed 2,000 feet per second.

In discussion Prof. J. A. Pope reminded the meeting that engineers are specially interested in the dynamic properties of metals. Under fatigue conditions the nature of the surface is most important: for example, light alloys tested with the as-extruded surface show much poorer properties than when the surface is carefully polished. Again, engineers are interested in machinability. If easily machined alloys are used, it might be possible to use water-cooled gas-turbine blades and to maintain a lower metal temperature by taking advantage of the stationary 'air' layer adjacent to the blade surface.

GENETICS AND EMBRYOLOGY

A DISCUSSION on the relations between genetics and embryology was held by Section D (Zoology) of the British Association on August 9. In introducing the topic, Prof. C. H. Waddington pointed out that when Bateson invented the word 'genetics' he defined it as the science which dealt with the physiology of descent, a phrase which could be held also to cover the subject which is usually known as experimental embryology. In spite of this, these two branches of biology, both of which have grown extremely rapidly in the past few decades, have developed almost in isolation from one another. After the disproof of at least the simple forms of the theory that differentiation is due to differential nuclear divisions, the concepts commonly used in them gradually diverged. Genetics came to envisage development in terms of the control of single chemical substances or enzymes by nuclear genes; while experimental embryology operated with the notions of gradients, on one hand, and active substances or regions, such as specific plasms or organizers on the other, neither of these types of agent being essentially connected with the nuclei. In quite recent years, these two categories of thought have begun to come together again. Thus, experimental embryology has been driven to recognize the fundamental importance of developmental competence, and to realize that this property is controlled, at least in the main, by genetical factors; while genetics has discovered that the connexion between gene and final product is not simple, but involves a balance between interacting forces which issues in a condition similar to the competence postulated by the embryologists. It may be hoped therefore that the natural unity between genetics and embryology will come to full expression in the near future.

Dr. R. A. Beatty then discussed some aspects of the importance of chromosomes in development, particularly in mammals. He described the occurrence of polyploids in mice. Triploid embryos are found to occur naturally in certain strains, and both triploids and tetraploids can be induced by hot shocks applied to the early stages of the eggs in the Fallopian tubes. So far no polyploids have been observed after birth; but the embryos appear to develop normally to mid-term, and it is hoped that polyploid young will shortly be identified. Turning to a rather different subject, he pointed out that evidence has been gradually accumulating that the cells of differentiated mammalian tissues may contain very different numbers of chromosomes. It does not seem plausible to attribute this to the technical difficulties of counting the chromosomes. There is no evidence that the type of differentiation is correlated with chromosome number; it seems more probable that neighbouring cells can co-operate, so that the important matter is the chromosome balance in the whole tissue rather than in the individual cells composing it.

Dr. D. S. Falconer pointed out that one approach to developmental genetics is to regard a mutation as causing a 'natural experiment'. It may be possible to show that the mutant gene produces some rather simple effect early in development and to trace a whole series of later modifications back to this original cause. As an example of such an approach, he described the analysis of a recent mutation in the mouse known as 'Crinkled'. The main initial effect seems to be the prevention of the formation of hair follicles except during a short period just before birth. This has a direct effect on the coat as a whole, which lacks the long guard hairs, normally initiated at an early period, as well as the short 'zig-zags', which are normally initiated after birth. It also explains the existence of certain localized bald patches, the absence of certain vibrissae, and, by its effect on the growth of the skin, the distortion of the vertebrae of the tail from which the gene gets its name, as well as a number of other minor effects.

After the discussion, a series of cinema films were shown, one of which demonstrated the technique used for inducing polyploidy in mouse eggs.

SHIPBUILDING

AN international conference of naval architects and marine engineers was held during June 25–30, with proceedings in London, Glasgow and Newcastle upon Tyne.

The first paper read in London, "Ships Structures —A Century of Progress", by Mr. R. B. Shepheard, of Lloyd's Register of Shipping, traced the development of ships' structures from the wooden ships in general use one hundred years ago, through the stages of iron and riveted mild steel to the modern welded steel ship. With certain noteworthy exceptions, progress following the introduction of new methods of shipbuilding has been delayed by persistent attempts to reproduce the traditions of the earlier methods in the new material.

The application of scientific principles to the structural design of ships developed from the earlier work of Grantham and Fairbairn about ninety years ago, until some forty years later rational methods of obtaining the distribution of material in the section of a ship were developed, largely due to the work of Foster-King, Bruhn and Isherwood. Since that time, research on the behaviour of ships' structures and component structural members has continued in order that further economies might be effected in the light of increased knowledge. The recent introduction of welding on a large scale has presented the designer with many new problems.

Developments of shipbuilding during the Second World War, particularly in the United States, brought to light the importance of notch toughness in mild steel, several major failures occurring due to lack of this quality. This problem of notch toughness which, so far as it relates to ship structures, was isolated in Great Britain in the Engineering Laboratory, Cambridge, as long ago as 1944, is being attacked by metallurgists and engineers in many countries.

Changes in the design and arrangement of dry cargo ships over the past fifty years have tended to increase the bending moments for the loaded condition at sea. In the case of the larger tankers, where there is considerable flexibility of loading in the ballast condition, a stage has been reached where the design must be developed with defined limitations on service schemes of loading.

Another paper, "Proposed Design for a Combined Research, Training and Cargo Ship", by Prof. H. E. Jaeger and J. C. Arkenbout Schokker, must have been of particular interest to shipbuilders in Great Britain owing to the very extensive work in the same field which is being carried out for the Admiralty Ship Welding Committee. It developed the interesting idea of building a dry cargo ship of about 9,500 tons deadweight which would serve the triple purpose of: (*a*) a training ship for officers and engineers for the merchant marine; (*b*) a research ship in which problems on ships' structures and performance could be investigated; and (*c*) a cargo ship engaged in normal trade partly to give realistic conditions for both training and research and partly to offset the cost of the project. This use of the ship for trading purposes would be subordinated to the needs of training and research.

The authors suggested that the most suitable size for such a vessel would be about 472 ft. length (B.P.) and 68 ft. breadth. The displacement would be 15,000 tons and the desirable speed 17 knots, requiring engines of about 8,700 S.H.P. The initial installation should be a diesel electric set installed aft with provision for the substitution of a gas-turbine motor at a later date. Suitable accommodation is planned for the large number of officer cadets and research workers, in addition to the normal complement.

The structure of the ship would include examples of several different types of construction. For example, the fore part would be longitudinally framed, whereas the after part would be transversely framed. Several different types of bulkhead stiffening would be fitted, including some corrugated bulkheads. All bulkheads would be designed to allow the holds to be filled with water up to the level of the shelter deck. This would enable large bending moments and other actions to be applied to the ship during structural tests. Various types of roll-stabilizing equipment would be installed for testing the relative merits of different systems.

No details were given by the authors of the equipment for measuring and recording the forces acting on the ship at sea and the strains induced in the structure. There would, of course, be the great advantage over the recent British experiments on the S.S. *Ocean Vulcan* that the installation of instruments could be made while the ship was under construction.

More rational methods of designing ship structures can only be developed with confidence when more is known of the actual forces to which the structure is likely to be subjected, so that the authors' proposal that several research ships should be built and operated in all parts of the world is attractive. Unfortunately, such experiments are costly, not only in the initial outlay on the ships and in their running, but also in the reduction to useful form of the vast amount of records collected on each voyage.

The cost of such full-scale experiments compels naval architects, as it does engineers in so many fields, to attempt to collect information from model tests such as those described by J. C. Niedermair, of the Bureau of Ships, in his paper "Ship Motions". The paper describes a series of experiments on the behaviour of five ship models of widely differing forms under steady wave conditions. In most of the tests a constant propelling force was applied to each ship in turn, and the amplitudes and periods of the resulting motions were measured together with the mean speed of advance through the waves. In the testing tank used, it was only possible to propagate waves the direction of advance of which was parallel to the ship's course. The full-scale dimensions of the waves used ranged from 300 ft. to 900 ft., and the full-scale heights lay between 19 ft. and 33 ft., while the lengths of the ships were from 380 to 550 ft.

Remarkable changes in the mean speed of advance were shown with changes in wave length. Despite a great difference in form of the ships, the five models showed like characteristics. Each model exhibited a minimum speed for constant propelling force when the wave-length was about equal to the ship's length.

Curves giving the pitch amplitude as a function of wave-length show that the ratio of maximum pitch to maximum wave slope continues to increase with increasing wave-length at least until the wave-length equals twice the length of the ship. It is significant that no irregularities occur in these curves around the value of wave-length which should theoretically cause resonant pitching. The experimental records have been related to the theoretical analysis recently published by Weinblum and St. Denis, and found to be in general agreement. The pitching periods during these tests were those of the period of encounter, although it is generally accepted that a ship in a seaway pitches usually to its own natural period. It appears that the severity of the forcing motion used has masked the natural oscillations of the ship.

Not unnaturally, the authors feel the need for the verification of the similarity of ship and model motions, and they point out that this would involve instrumenting a ship fully, both to record ship motions and to record simultaneously the surface of the sea. All ways, therefore, seem to point to the need for more research ships.

CANCER RESEARCH IN GREAT BRITAIN

TWO annual reports which have recently been published, those of the Imperial Cancer Research Fund* and of the British Empire Cancer Campaign†, record the slow but steady progress that has been made in cancer research during the past year. The report for 1948 of the Imperial Cancer Research Fund gave first place to an account of certain investigations which lent weighty support to the virus theory of cancer, in that it was thought that what had been done since the classical work of Peyton Rous in 1911 on the chicken tumour could be reproduced on a mammalian tumour. It had been shown in the Fund's laboratories that mouse tumours could be frozen and dried, yet could still be successfully transplanted into mice. Freeze-drying kills cells but not viruses, and so it is considered that mouse tumour is transmitted by a virus liberated from the killed tumour cells.

The assumption of this essential condition did not survive tests at some other centres of cancer research. It was soon shown that freeze-drying, if carried to a more-or-less advanced stage, still leaves some viable cells which can be demonstrated by their growth in tissue culture. The positive results on inoculation can therefore be explained without invoking a virus as the agent for transmitting the tumour.

In the present report, the director of the Fund, Dr. James Craigie, frankly states that the mammalian virus hypothesis of tumour transplantation can no longer be considered. He has found, however, that the cells of a mouse tumour contain, in addition to the usual neoplastic cells, another type of cell characterized by being highly resistant to freeze-drying and by its high refractility. It can only be recognized by phase-contrast microscopy. He suggests that the cells of some tumours can assume the refractile state and that these cells can also change back into "normal tumour cells". The analogy with spore formation of micro-organisms is obvious.

The refractile cells are very potent tumour-carriers; only seventy-five cells are required to produce a tumour on inoculation into mice. "It has been found possible to obtain them (refractile cells) in considerable quantity for study, either by fractionating suitable suspensions prepared from subcutaneous tumours or by collecting them from the fluid which accumulates when tumour growth is produced by intraperitoneal inoculation . . . it was found that the refractile bodies were not stable in vitro but might change into recognizable tumour cells. . . . The discovery that the cells of some tumours assume this resistant state raises a number of questions. . . .". Clearly, these observations are of great importance and their development should do much to stimulate the biology of cancer.

Other studies at the Fund's laboratories at Mill Hill include those of L. Foulds on the responsiveness of some mouse mammary tumours to the hormonal influences which operate during parturition and lactation. An attempt is being made by P. C. Williams to induce similar effects by supplying hormones artificially to female mice bearing this type of tumour.

H. G. Crabtree has as yet found no straightforward relationship between the liver cancer inducing potency and the chemical structure of a series of azo-carcinogens. Reduction fission of the azo-compound yields a diamine moiety which selectively inhibits enzymes the activity of which is dependent upon intact sulphydryl groups; however, the correlation between carcinogenicity and potential inhibition shows some discrepancies.

E. Vazquez-Lopez finds that administration of thiourea to virgin mice of cancer-liable strains causes a significant decrease in the incidence of mammary cancer. After treatment by thiourea the œstrogenic secretion is re-established and mammary tumours begin to appear. These experiments suggest that "oestrogens are active carcinogenic agents independently of their primary morphogenetic functions".

Of the scores of researches described in the report for 1950 of the British Empire Cancer Campaign, the most attractive is by Sir Ernest Kennaway. Sir Ernest, who has recently celebrated his seventieth birthday, is too well known for his achievements in cancer research to need reiteration; the enigma of neoplasia has been compared to an uncharted ocean, and on this basis he could be called its Columbus. One of the reasons for the extraordinary interest of his essay is that it does squarely face the problem of the cause of cancer.

Cancer of the lung has undergone an immense increase of incidence in recent years—four times as high in an interval of fifteen years. Is this multiplication due to an increase in the inhalation of carcinogens, benzpyrene in town smoke or of arsenic in tobacco smoke? The analysis of twenty-seven brands of cigarettes shows that British, Canadian, American and Norwegian cigarettes contain the largest amount of arsenic (24–106 μgm./gm.), and Bulgarian the least, 0–1·2; Turkish tobacco contains little arsenic, 0–4·3. Nevertheless, the incidence of lung cancer is very high in Istanbul, for in 1946–48 the percentage of cancer of lung was thirty per cent of all cancer autopsies in males. In autopsies at St. Bartholomew's Hospital, London, the comparable figure was 41·17 per cent. Although no simple relation can be thus shown between lung cancer and arsenic in tobacco, the possible synergistic effect of this carcinogen cannot be ignored; a smoker can volatilize half a milligram of arsenic a day. Certain occupations have a low lung-cancer incidence, namely, agriculture, coal mining and mule spinning. The workers in the two last-named cannot smoke for a third of the day, and, in the first, atmospheric benzpyrene from town smoke is at a minimum. The aeration and temperature of the glowing tip of a cigarette is such as to render the production of benzpyrene negligible. In town smoke this carcinogen is due to the agglomeration of active domestic chimneys, for it is not emitted by properly working industrial furnaces or generating stations. The part played by other associated factors has still to be investigated—for example, the size of the particles in smoke containing the benzpyrene and the chances of these being retained in the bronchi and lungs, and secondly, the carcinogenic effect, if any, of components in the exhaust gases of motor vehicles.

"The finely divided carbon (in human lungs) . . . represents the intake of a lifetime. . . . The carbon itself may be innocuous, but from the study of atmospheric pollution . . . one can form some idea of the amount of benzpyrene which would accompany it. The small amounts of radioactive material, and of arsenic, which have been found in the dust of towns incline one to attach more importance to benzpyrene in this respect, but one must remember that: (*a*) we have no data upon the minimum effective dose of any carcinogen in man; and (*b*) we do not know whether the effects of different carcinogens upon the same tissue can summate."

---

* Forty-Eighth Annual Report of the Imperial Cancer Research Fund, 1950–1951. (Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.)

† British Empire Cancer Campaign. Report for 1950. Edited by Sir Heneage Ogilvie. (11 Grosvenor Crescent, London, S.W.1.)

Cancer of the larynx has increased of late years but not so rapidly as lung cancer, and this disease also shows a sex difference. Sir Ernest, in explanation, advances the stimulating idea that: "The differences in the anatomical, social and geographical distribution of cancer of the larynx in men, and in women, show that these two must be regarded as, to a large extent, different diseases; any statistics in which they are pooled are of no value. The larynx is a secondary sexual organ, hence such differences are not surprising. The adoption of smoking by women, and the increased consumption of tobacco and especially of cigarettes, by both sexes, has not affected the absolute numbers of cancers of the larynx in recent years; there has been no uniform change in either sex since 1930. As recently as 1929 the numbers of cancers of the larynx, and of the lungs, in males was about equal . . . since then, the deaths attributed to the latter have increased enormously".

After these examples of scientific thought and language, the approach to the rest of the report requires some little mental readjustment; most of the material presented is very technical and will be of great interest, and of course is mainly intended, for research workers engaged on closely allied branches of work.

Specialization is inevitable; but it carries with it a danger for cancer research, for each step in development implies more refined technique and more recondite treatment, and consequently there sometimes arises a tendency to encourage the pursuit of the means rather than the end.

A long report from the Clinical Cancer Research Committee on cancer of the lip, mouth and tongue is concerned chiefly with the compilation of abundant data rather than the extraction of generalizations.

Apart from the investigations mentioned so far, the principal themes of research have been threefold: physics and radiology (developments in radio-therapy, and changes in tissue brought about by X-rays); 'model experiments', that is, the study of changes induced in genic material and structures; and carcinogens and carcinogenesis.

The attention devoted to chemotherapy is rather less than in previous years; much more emphasis is being laid on the lines of the 'model experiments'. The agents used for investigation have been radiations, mitotic poisons, nucleotoxins, carcinogens and mutagens; the test objects have been cells in tissue culture, chromosomes, genes and nucleoproteins. The precise relation of this voluminous work to cancer is perhaps not obvious to the uninitiated. It depends upon the thesis that cancer is an aberration of growth, development, repair and differentiation, that these four features of cells and tissues depend in turn on the nucleus of the cell, that the dynamics of the cell are an expression of the structure, metabolism and influence of the nucleoproteins, and, finally, that genes and viruses have largely the same type of chemical nature.

J. F. Danielli and collaborators have succeeded, using microdissection, in transplanting the nuclei of two amœbæ giving an *Amœba proteus* nucleus living in an *Amœba discoides* cytoplasm. The next step is plain: these investigators should now try to transplant the nucleus of a tumour cell into the enucleated cytoplasm of a normal cell.

The histological alterations in the epidermal tissue of the mouse after X-radiation has been examined by A. Glucksmann, who found that destruction of the epidermis, hair follicles and superficial parts of the derma is followed by regeneration, scarring, a breakdown of the scar tissue and a repetition of the whole process, without further radiation, which finally gives rise to squamous cell cancer.

J. W. Orr and co-workers have transplanted mouse skin, which had previously been painted with methylcholanthrene, on to some other part of the mouse; the striking fact has been revealed that the decisive pre-cancerous change has been effected in the sub-epithelial tissues although the methylcholanthrene-induced cancer arises in the epithelial cells: ". . . when the stroma has been adequately prepared by carcinogenic treatment it is not necessary that the epithelium growing on it should have been itself exposed to a carcinogen before carcinoma can occur. It also appears that carcinogen-treated epithelium may not become neoplastic when transferred to a healthy bed."

Two items dealing with cancer of the liver are also included: the report from the South African Cancer Association refers to the extreme susceptibility of the Bantu to liver cancer (forty times as high as in Europeans); C. Berman has now published his admirable studies in this field of cancer research in the form of a monograph, "Primary Carcinoma of the Liver" (H. K. Lewis, London).

ROYAL GREENWICH OBSERVATORY

ANNUAL REPORT

THE report of the Astronomer Royal to the Board of Visitors of the Royal Greenwich Observatory*, presented at the annual visitation held on June 2, covers the period May 1, 1950–April 30, 1951, and exhibits the state of the Observatory on the last date. Only some of the more outstanding matters of general interest can be mentioned here.

Many will regret the fact that Flamsteed House, including the Octagon Room, is no longer under the jurisdiction of the Royal Observatory, as it has been converted into two flats for naval officers of the Royal Naval College. The Wren Building, taken over by the Ministry of Works, will be treated as an ancient monument, and repair work is now in progress. At Herstmonceux no work has yet started on the sites of either the meridian group or the equatorial groups, but the exact locations for the individual meridian instruments have been selected. Work has not proceeded as anticipated in the previous year's report, which stated that the building for the Cooke reversible transit circle was not expected to be completed before the spring of 1951; that the building for the photographic zenith tube was planned to be completed in the summer of 1951, and the pavilion for the Melbourne reversible transit circle by the middle of 1952. In addition, it was hoped that the buildings for the 26-in. and 28-in. refractors would be completed during 1952; but unfortunately no further building has been started, and it seems improbable that the target date of the end of 1953 for the completion of the removal of the Observatory to Herstmonceux will be attained.

---

* Report of the Astronomer Royal to the Board of Visitors of the Royal Greenwich Observatory read at the Annual Visitation of the Royal Observatory, 1951 June 2. Pp. ii+20. (Greenwich: Royal Observatory, 1951.)

The report follows the usual lines of those of previous years; but one matter is worth special attention as it contains great possibilities for the future. On the suggestion of Prof. R. O. Redman, long exposures were made on regions containing the most intense discrete sources of galactic radio noises, and it is intended to repeat the plates after a year to discover whether any very faint object shown has a large proper motion. Three first-epoch plates have already been secured in the direction of the source in Cassiopeia, three towards that in Coma Berenices, and one towards that in Cygnus. One second-epoch exposure on the Coma source has shown that the method used is unsuitable for the detection of a small displacement in one object among scores to be examined. A different procedure will be adopted in the future; second-epoch plates will be taken direct, and glass positives, prepared from the second-epoch plates or from the earlier plates, whichever happen to be the more exposed, will be used for detecting any proper motion that may be large enough to be seen.

As a result of the work on the solar eclipse of November 1, 1948, it seems possible that improvements could be made in the method by which the limb-contours were being reduced in Washington. The observers at Washington have sent an improved contour for librations corresponding approximately with the librations at the time of the eclipse, and plans have been developed for a more extensive application of the method at the total eclipse of February, 1952. It is proposed to make observations at two places near Khartoum which just lie outside the region of totality on both sides of the central line, and also at two places near Basra, similarly placed with respect to the central line. Long-focus cameras will be used at the Khartoum sites to photograph the eclipse with the object of obtaining the precise contour of the moon's limb during the eclipse.

About four pages are devoted to the work of the Nautical Almanac Office, and one rather disconcerting matter is mentioned at the beginning of this report. Although the junior staff has been up to its complement for the greater part of the year, it has not been possible to fill the vacant post of 'scientific officer', which has been unfilled since 1945. In the *Almanac* for 1952 three major changes which were announced in 1951 have been made; eighteen pages have been devoted to ephemerides of Ceres, Pallas, Juno and Vesta. The list of apparent places of stars has been replaced by an extended list of mean places of stars; elements of occultations have been omitted, but apparent places of occulted stars (pp. 321–329 in the *Almanac* for 1952) have been retained. The occultation machine, designed by Mr. J. D. McNeile and built by Mr. A. C. S. Westcott, has undergone a number of improvements, among which may be noticed that to the 'moon' system. The work was carried out at the National Physical Laboratory to a design by Dr. D. S. Perfect, to allow greater accuracy in setting the limb of the moon on a station and in other ways to provide more satisfactory results. Preliminary tests have shown a great improvement in accuracy; but at present it is impossible to say whether the times as determined by the machine will dispense with the necessity for prediction computations. The new form of *Abridged Nautical Almanac* for 1952, a preliminary notice of which has aroused considerable interest, was not published at the time of the compilation of the report, but has since appeared.

It is very satisfactory to know that so far the experience of observational conditions at Herstmonceux shows they are up to expectations. Over a period of nearly a year the amount of sunshine at Herstmonceux has been nearly fifty per cent higher than at Greenwich, the greatest excess of sunshine at Herstmonceux occurring in the afternoon; the greater amount of cumulus cloud at Greenwich is responsible for the difference. Although the night sky records at Herstmonceux show only a moderate excess of clear sky, the transparency there is much better than that at Greenwich, and the average definition is also superior. It is anticipated that the freedom from the glare of artificial lights at Herstmonceux will be of great benefit in all types of observations, and the staff is eagerly looking forward to the commencement of night observations free from the difficulties under which they were carried on at Greenwich for many years.

DEPARTMENT OF SCIENTIFIC RESEARCH, INDIA

THE report of the Department of Scientific Research, India, for 1950–51* states that investigations on atomic energy continued in research institutes and university laboratories all over India, and that important results have been obtained in the study of cosmic rays. A factory capable of processing annually 1,500 tons of monazite to give 207 tons of thorium nitrate, 1,500 tons of rare earth chlorides and 1,800 tons of trisodium phosphate will be completed during the present year. Valuable deposits of uranium and beryl have been discovered. An International Conference on Elementary Particles was organized at the Tata Institute of Fundamental Research, Bombay, during December 14–24, 1950. The Advisory Committee for Co-ordinating Scientific Work, presided over by the Prime Minister, reviewed the work and functions of the various departmental scientific committees and has established a scientific advisory committee to study and advise on methods of broadcasting, as well as a committee to consider the establishment of national parks and Nature reserves for the preservation of flora and fauna.

A directory of type cultures maintained at various places in India is being prepared, and attention has also been given to the improvement of the cultivation of pyrethrum plants and of the extraction, stabilization and formulation of pyrethrin. With assistance from the United Nations Educational, Scientific and Cultural Organization, an Indian National Bibliographical Centre is being established and this may also be developed into a national library. Sir C. V. Raman has continued his work on the diffusion of light in transparent media. Besides encouraging the study of geophysics in the universities, the Central Board of Geophysics is seeking to set up a central geophysical institute.

---

* Report of the Department of Scientific Research for 1950–51. Pp. 22. (New Delhi: Department of Scientific Research, 1951.)

The Council of Scientific and Industrial Research records the opening during the period of seven national research laboratories: the National Chemical Laboratory, Poona, on January 3, 1950; the National Physical Laboratory, New Delhi, on January 21, 1950; the Fuel Research Institute, Dhanbad, on April 22; the Central Glass and Ceramic Research Institute, Jadavpur, on August 26; the Central Food Technological Research Institute, Mysore, on October 21, 1950; the National Metallurgical Laboratory, Jamshedpur, on November 26; and the Central Drug Research Institute, Lucknow, on February 17, 1951. The programme of work to be undertaken by these laboratories is indicated in the report. In addition, six regional coal survey stations are being set up to survey the coal resources of India.

The Central Road Research Institute, New Delhi, is studying the vitrification of bricks for road use, the improvement of bullock cart wheels and jointing compositions for aerodrome runways. The Central Building Research Institute, Roorkee, is investigating the use of indigenous building materials for houses, water-proofing agents to supplement the stabilizing action of lime sludge from sugar factories and problems in the manufacture of bricks. The use of myrobolan extract in the South India tannage and the manufacture of synthetic tannins from cashew shell and Bhilawan nuts are being examined at the Central Leather Research Institute, Madras.

Research schemes sanctioned by the Council during the year included the following topics: development of heavy-duty parts of internal combustion engines, hot-air engines and gas turbines and jet propulsion units; investigations of Indian medicinal plants, proteins from green leaves, gases in steel, and radio valves; and the manufacture of alcohol from bagasse and other agricultural wastes, of aluminium metal by electrolysis, of anhydrous aluminium chloride and of synthetic sapphires.

A Board of Engineering Research, with five expert committees, has been established.

The report also outlines the broad policy to be followed by the national laboratories in giving technical assistance to industry.

SCIENTIFIC RESEARCH IN INDUSTRY IN BELGIUM

THE annual report, for 1950, of the Institute for the Encouragement of Scientific Research in Industry and Agriculture, Belgium*, records a distribution during the year of grants totalling 69,202,500 francs. Of this total, 16,715,000 francs went to the committee on mapping the soil and vegetation of Belgium for making a systematic survey of the pedological characteristics of Belgian soils and completing a pedological map of the kingdom, and 6,438,000 francs to the committee for the study of the diseases and nutrition of livestock, and particularly trichosomiasis and brucellosis. A subsidy of 5,607,000 francs was allotted for the construction of an electronic calculating machine, and one of 5,281,000 francs for investigations, during two years, on the improvement of the quality of milk and problems of interest to the butter and cheese industry. A grant of 5,120,000 francs was made for research on rational and intensive exploitation of grasslands in Belgium, and another of 4,300,000 francs for investigations for improving the development of orchards, including soil investigations, studies on fruit trees and their culture and the diseases of fruit and their prevention. The Institute granted 2,800,000 francs for the investigations on industrial and potable water and the treatment of effluents, and 1,950,000 francs for scientific and technical investigations on the culture of vegetables for preservation, the selection of varieties and on the biological, chemical and physical conditions for preservation.

Grants were also made of 1,492,000 francs for chemical and physico-chemical researches on high polymers, including the study of dielectric constants, and of thermodynamic properties, the fractionation of polymers and investigations on the co-polymerization of styrene with drying oils, the dissolution of acrylonitrile and the thermal stability of polyvinyl acetate; 1,230,000 francs for investigations on soilless culture directed to the determination of practical conditions and to the study of physiological aspects of mineral nutrition of general interest in agriculture; and 890,000 francs for investigations on the improvement of the cultivation, conservation and utilization of medicinal and aromatic plants. The Union for Electrical Development in Belgium received 850,000 francs for continuing its researches on furnace refractories. Grants totalling 820,000 francs were given for researches on medicinal plants collected during 1947–48 in the Belgian Congo, and 779,500 francs for genetic, entomological and technological investigations on both Belgian and Congo timber. The Belgian Institute for High Pressure received a further 771,000 francs for continuing its piezometric studies, its studies on manometric balances, and on the biological effects of high pressures, while 762,500 francs was given for research on the proteins of barley and malt, and 700,000 francs for the continuation of work on the effect of oxygen excess in the blast vent of the Thomas steel plant.

Smaller grants were made for the following purposes: road research (514,000 francs); mushroom cultivation (485,000 francs); improvement and cultivation of the strawberry plant (400,000 francs); manufacture of calcium cyanide (480,000 francs); behaviour of asphalt mastics (380,000 francs); plasticity of ceramic doughs (277,500 francs); organic matter in Belgian soils (228,000 francs); Belgian Institute of Welding for research on the use of ultrasonics for the auscultation of welds (227,500 francs); preliminary investigations on the utilization of metals (222,500 francs); use of explosives in mining demolition and in quarrying (168,500 francs); preservation of perishable produce by rapid freezing (121,000 francs); and for investigations on air liquefiers (85,000 francs).

A list of publications relating to researches subsidized between October 1, 1949, and December 31, 1950, is appended, and the Institute has also issued a pamphlet summarizing briefly its activities since it began to operate in 1945, showing the results achieved by the expenditure of some 240 million francs distributed over 173 subsidies.

Terminology for Use in Lactational Physiology

Recent advances in the elucidation of the physiological mechanisms of lactation, particularly those mechanisms concerned in the transfer of milk from the mammary glands to the young, have revealed inadequacies and ambiguities in the terminology in common use in relation to lactational physiology. An example of such an ambiguity is the term 'to suckle', which is at present being used to denote the activity of the lactating mammal or the young or both. In 1947, one of us[1] proposed a scheme, now generally adopted, which classified and defined the major physiological components of the total phenomenon which is called 'lactation', and which has done much to clarify terminology in this field. We should now like to put forward additional terms which, if generally accepted, we believe will render the above-mentioned scheme more comprehensive and will largely resolve the ambiguities still in existence.

The terminology we propose is as follows:

Nursing. The behaviour of the lactating mammal in promoting access of the young to the nipples or teats.

Suckling (milking). The activity of the young (or operation of the milking device) with the aim of obtaining milk from the mammary glands.

Suckling (milking) stimulus. The sum of stimuli applied to the lactating mammal by suckling (or milking).

Alveolar milk. The milk stored in the lumina of the alveoli and ducts of fine calibre.

Sinus milk. The milk stored in the ducts of large calibre and lactiferous sinuses or cisterns.

Passive withdrawal. The removal of sinus (or cistern) milk which at low intramammary pressure can be brought about by the action of suckling or milking or by cannulation without the intervention of the special contractile tissue of the mammary glands.

Milk ejection. The effect of alveolar contraction elicited reflexly by the suckling or milking stimulus in mammary glands distended with secretion. It involves the movement of some alveolar secretion into the sinus or cistern (that is, alveolar discharge) thereby producing a rise in intramammary pressure (hitherto called 'let-down' or 'draught'). Milk ejection may or may not involve passage of milk to the exterior.

The scheme of Folley[1], illustrating the phases of lactation may thus be extended as follows:

- Lactation
  - *A.* Milk secretion
    - (*a*) Synthesis of milk by the cells of the alveolar epithelium
    - (*b*) Passage of milk from the cytoplasm of the alveolar epithelial cells into the alveolar lumen
  - *B.* Milk removal
    - (*a*) Passive withdrawal
    - (*b*) Milk ejection

It is hoped that the terminology proposed will cover the phenomena formerly described by 'let-down', 'hold-up', and 'draught' in agricultural and medical circles, and that these latter terms will no longer be used, at least in scientific literature.

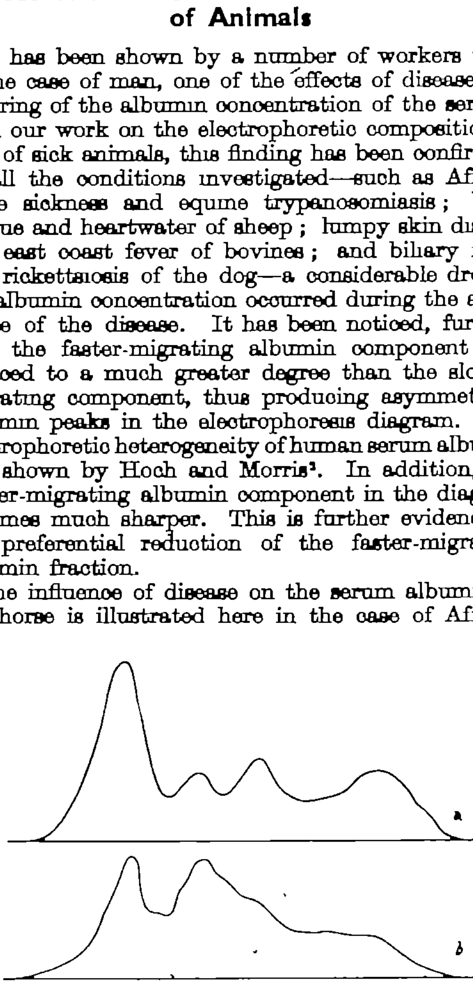
Effect of Diseases on the Serum Albumin of Animals

It has been shown by a number of workers that, in the case of man, one of the effects of disease is a lowering of the albumin concentration of the serum[1].

In our work on the electrophoretic composition of sera of sick animals, this finding has been confirmed. In all the conditions investigated—such as African horse sickness and equine trypanosomiasis; bluetongue and heartwater of sheep; lumpy skin disease and east coast fever of bovines; and biliary fever and rickettsiosis of the dog—a considerable drop in the albumin concentration occurred during the acute phase of the disease. It has been noticed, further, that the faster-migrating albumin component was reduced to a much greater degree than the slower-migrating component, thus producing asymmetrical albumin peaks in the electrophoresis diagram. The electrophoretic heterogeneity of human serum albumin was shown by Hoch and Morris[2]. In addition, the slower-migrating albumin component in the diagram becomes much sharper. This is further evidence of the preferential reduction of the faster-migrating albumin fraction.

The influence of disease on the serum albumin in the horse is illustrated here in the case of African



Electrophoresis diagrams of the serum of the susceptible horse (*a*) before inoculation with horse sickness; (*b*) at the peak of the reaction to African horse sickness horse sickness. Fig. *a* shows the electrophoresis diagram of the serum of a susceptible horse; Fig. *b* is the diagram of the serum taken at the peak of the reaction to African horse sickness in the same horse after experimental infection. The dissimilarity between the two diagrams is obvious. In this communication attention will be paid only to the albumin component.

In the serum of the horse taken at the peak of the reaction the albumin component is reduced considerably and becomes quite sharp and asymmetrical. There is a distinct bulge on its side which indicates that the faster-moving albumin constituent is reduced in concentration. In normal serum at *p*H 8·6 at which these measurements were made, the two components migrate with velocities which differ only by a few per cent. It is only when the concentration of one component is reduced that the heterogeneous nature of the albumin is noticed.

So far as I am aware, the selective reduction of the albumin through the influence of a disease has not been reported by other workers in this field. This is due to the relative insensitivity of the usual optical methods employed in electrophoretic studies, as compared with the very sensitive Lamm-scale method used in this work.

Cocarboxylase in Experimental Diabetes

In previous experiments we have found that the injection of cocarboxylase causes, in the alloxan-diabetic rat, a diminution of the blood sugar and an increase of the respiratory quotient and of tissue glycogen. Thiamine produces similar effects; however, with severely affected animals it fails to act[1,2]. The hypothesis was then advanced that, in severe alloxan diabetes, thiamine does not produce any effect because its conversion to cocarboxylase is prevented. We have now obtained some evidence in support of this hypothesis.

According to Ochoa[3], the phosphorylation of thiamine occurs mainly in the liver; we have therefore estimated the cocarboxylase in this organ of the alloxan-diabetic rat after injection of thiamine.

Table 1. Stock rats of both sexes of 200 gm. approximately were used. Thiamine hydrochloride 20 mgm./kgm. body-weight by intramuscular injection; animals killed by decapitation 30 min. after the injection. Cocarboxylase was determined by the method of Ochoa and Peters (ref. 4) with minor adaptations (ref. 5)

Rats	No. of animals tested	Liver cocarboxylase (μgm./gm. wet tissue)	
		Range	Average
Normal	22	7·70–12·91	9·62 ± 0·28
Diabetic	25	3·24–6·39	4·57 ± 0·16
Normal + thiamine	15	16·40–24·45	20·49 ± 0·67
Diabetic + thiamine	15	3·60–11·10	6·69 ± 0·61

It will be seen from Table 1 that in alloxan-diabetes a significant decrease of the cocarboxylase content of the liver occurs. This reduction was usually higher in those animals more severely affected. In the normal animals the injection of thiamine was followed by an increase of the liver cocarboxylase; this increase occurred in all the animals tested and exceeded 110 per cent.

In the diabetic rats the injection of thiamine was also followed by an increase of the liver cocarboxylase; however, this increase was much less than in the normal animals.

To see whether a relation existed between the respiratory quotient of the diabetic rat after injection of thiamine and the concentration of liver cocarboxylase, we have measured the respiratory quotient just before the injection of thiamine (20 mgm./kgm.) and glucose (5 gm./kgm.), and 60 min. later; after a few hours, another dose (20 mgm./kgm.) of thiamine was injected and the liver cocarboxylase determined.

The animals more severely affected by diabetes failed to show an appreciable increase of respiratory quotient; in these animals the cocarboxylase content of the liver remained very low, of the same order of that found in the untreated diabetic rats. On the other hand, in animals which showed an increase of the respiratory quotient after injection of thiamine, the liver cocarboxylase was considerably increased. Two typical results are given in Table 2.

Table 2. Respiratory quotient (R.Q.) measured by the method of Haldane-Margaria (ref. 6). Cocarboxylase determined a few hours after the R.Q. and 30 min. after an additional dose (20 mgm./kgm.) of thiamine

R.Q. of diabetic rats		Liver cocarboxylase (μgm./gm. wet tissue)
Before	60 min. after thiamine + glucose	
0·65	0·67	3·80
0·74	0·95	13·74

These results indicate that in alloxan-diabetes the phosphorylation of thiamine is partially or completely inhibited; by analogy, they could also offer an explanation for the high levels of blood keto-acids found in severe pancreatic diabetes.

We think that the lack of available insulin which characterizes the diabetic condition is the primary cause of the phenomena described.

A full report of this work will appear elsewhere.

The Gelatinous Mass in Rabbit Semen

Rabbit semen consists of two main parts, gelatinous and fluid. After ejaculation, the gelatinous part fills the lumen of the vagina as a copulation plug (*bouchon vaginal*). The existence of a copulation plug, which prevents the semen running out of the vagina after ejaculation, has been observed[1] in a number of mammals besides rodents. Its importance in rats for fertile mating has been shown by Blandu[2]. That the production and maintenance of the gelatinous mass which mainly constitutes the copulation plug in the rabbit depends on testosterone has been shown by Parsons[3]. She found that castration in rabbits leads to complete absence of the gelatinous mass in ejaculates. When testosterone propionate was injected into such castrated rabbits, the gelatinous mass reappeared. She further found that implantation of stilbœstrol tablets into a buck previously castrated and implanted with testosterone brought about an inhibition of sex drive as well as a sharp decrease in seminal fructose, but an increase in the gelatinous part. This increase in the gelatinous part, however, remained unexplained.

With the view of finding out the significance of the gelatinous mass in rabbit semen in normal mating, semen samples from six bucks were obtained in an artificial vagina. It has been found that the gelatinous mass per ejaculate varied from 0·34 to 4·19 gm., the average being 1·67 ± 0·36 gm. Fructose, the seminal nutrient for spermatozoa[4], is present in the fluid portion. The thoroughly washed gelatinous portion, when examined for fructose by the technique described by Mann[5], was found to have an almost negligible quantity. Incubation of semen samples with and without the gelatinous mass at the vaginal temperature of rabbit (namely, 40° C.) has shown that the rate of utilization of fructose in semen is positively correlated with sperm concentration of the sample. The rate, however, is uninfluenced by the presence or absence of the gelatinous mass.

Examination of the thoroughly washed gelatinous mass under the microscope revealed a large number of inactive spermatozoa encased in it. On incubating the mass at 37° C. in normal saline, it dissolved and the spermatozoa thus released were found to be highly active. The encasement of spermatozoa by the gelatinous mass is perhaps due to the fact that at the time of ejaculation both parts of the semen are in a fluid state. Subsequent gel formation of one part encases some of the seminal fluid containing spermatozoa in contact with it.

It has also been found that 800 mgm. of the gelatinous mass dissolved in 8 ml. of water at approximately 80° C., when injected subcutaneously after cooling in four equal doses with two injections a day at an interval of 8 hr. between the two injections into ovariectomized immature rats, produced keratinization of the vaginal cells after 96–120 hr. from the first injection. Similar results have been obtained by injecting 400 mgm. of the mass dissolved in 4 ml. of hot water into ovariectomized mice of approximately one month old. Subcutaneous injections were also given to eight adult male rats each of which received, in six equal doses with two injections a day, altogether 1·2 gm. of the mass in 12 ml. of water. The rats were killed on the ninth day from the first injection, and the histological examination of their testes revealed degeneration of the seminiferous tubules. There was also significant decrease in the weight of the seminal vesicles and a highly significant decrease in their fructose content compared with those of the control rats of the same age and body-weight. These findings, therefore, indicate that the gelatinous mass appears to contain œstrogenic substance in appreciable quantity.

Light-scattering Studies on Penicillin G Solutions

Literature concerning the physical-chemical state of aqueous systems of penicillin reveals a controversial issue. Claims that micelles, between 200 A. and 5000 A. in length, are formed above a critical concentration of 10,000 units/c.c. (0·6 per cent)[1-4] contrast with evidence which indicates that penicillins behave as simple electrolytes[5-8]. One paper[8] reports that colloidal electrolyte behaviour is not reached until 8·26 per cent, a concentration so high as to be of little biological importance.

In view of this controversy, a light-scattering technique, as used by Debye[10], which permits precise measurements of scattering over a wide angular range and which is admirably suited for studies of micelle systems, has been applied. From determinations of the dependence of turbidity and of the refractive index on concentration, molecular weights can be found by use of the well-known equation[11]:

$$\frac{1}{M} = \frac{32\pi^3}{3}\,\frac{\mu_0^2}{\Lambda\,\lambda^4}\left(\frac{\mu-\mu_0}{c}\right)^2 C/\tau$$

Furthermore, by analysis of the angular dependence of the scattered light, information about the size and shape of micelles is possible.

Studies have been made using Wyeth crystalline potassium penicillin *G* (Lot *EKD* 500804 containing 1,650 units/mgm.) in the concentration-range 3,000–30,000 units/c.c. A solution in water, at a concentration of 10,000 units/c.c., exhibits much less scattering than that of systems containing micelles as large as those previously reported for penicillin at that concentration[3]. For this reason, further studies have been made in solutions containing electrolytes, a condition which enhances micelle formation. Also, in the presence of electrolytes, aqueous solutions can be readily freed from dust particles by filtration through very fine sintered glass, and thus a danger which may lead to spurious observation of micelles is removed. In potassium bromide solutions of ionic strength 0·2 and 0·5 respectively, the angular scattering, about 90° over the whole concentration-range, exhibits perfect symmetry (Fig. 1).

Unless a scattering particle has some dimension greater than about one-tenth of the wave-length of the exciting radiation, no dissymmetry in the scattered light can be detected. In this case the symmetrical scattering reveals that, apart from the possible existence of a minute fraction of large particles, any particles present have a maximum dimension not greater than 300 A. For the same systems the value obtained by extrapolation of the linear graph of concentration divided by turbidity (C/τ in the equation) is 35 at zero concentration (Fig. 2). The refractive increment $(\mu - \mu_0)/c$ can be

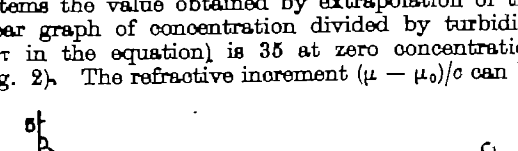

Fig. 1. Relative scattering intensity (I) of unpolarized light (λ = 4358 A.) by potassium penicillin *G* (13·9 mgm./c.c.) in 0·5 *M* potassium bromide

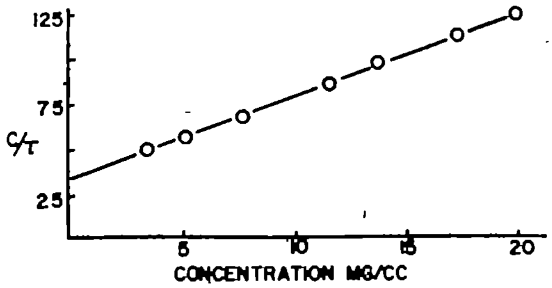

Fig. 2. Concentration-turbidity dependence for potassium penicillin *G* in 0·5 *M* potassium bromide

expediently determined with a differential refractometer and has a value of 0·185. Since these figures indicate a very low scattering system, in contrast to that expected from other work[3], we can ascribe a value of 3,000 as an upper limit to the molecular weight of any particles present.

The angular scattering data, Fig. 1, which indicate no dissymmetry, at once place an upper limit of 300 A. on any particles which may be present. In addition, the molecular weight maximum also dismisses the existence of large micelles of potassium penicillin *G* in the above concentration-range. Thus, although potassium penicillin *G* is slightly capillary-active, as evidenced by a small degree of frothing on shaking its solutions, the bulk phase contains associations of relatively few molecules even under conditions which enhance micelle formation and which also resemble more closely those encountered in biological systems.

I am indebted to Dr. F. Bueche for his interest and helpful discussions.

So-called Non-adaptive or Neutral Characters in Evolution

The reaction that set in some thirty years ago against the facile assumption that all interspecific differences are adaptive was good but went too far. Several authors insisted that most specific and subspecific differences were non-adaptive. More recently, Mayr[1], while emphasizing the great importance of selection in speciation, considered that not all geographical variation is adaptive and, in particular, that most of the characters involved in polymorphism are completely neutral so far as survival value is concerned. Later[2], he reversed this judgment on polymorphism.

Carter[3] places considerable emphasis on neutral characters, quoting as evidence banding in the polymorphic snail *Cepaea nemoralis*, Mayr's demonstration of apparently irregular variation in populations of *Cacatua galerita triton* in New Guinea, and the distribution of certain third chromosome inversions in *Drosophila pseudo-obscura*. But Mayr himself points out (ref. 1, p. 89) that size variation in *Cacatua* is not random except perhaps for the population on Biak (and Mayr and de Schauensee[4] have shown that the birds of Biak, which may be in part a very old island, are often different from those of nearby territories). Dobzhansky and others[5] have shown that the inversions are definitely subject to selection; and Cain and Sheppard[6] have demonstrated that variation in *Cepaea*, so often quoted as random, is, in fact, selectively controlled. Other examples quoted by Carter show an apparent randomness of variation, and he considers that it is difficult to see how the characters concerned could have any concomitant effects which might themselves be subject to selection. This is the real basis for every postulate of random variation or (more recently) genetical drift. The investigator finds that he, personally, cannot see any correlations in a given example of variation, and concludes that, therefore, there is none.

In view of the complexity of living things and their environment, a more cautious approach should be used. So far, every supposed example of random variation that has been properly studied has been shown to be non-random. One must agree that some characters have no value in themselves. But when it is found that their variation is stably clinal or otherwise correlated with their environment and history, then selection acting on their concomitant effects must be admitted as the governing factor. Mayr[1] gives many examples. He contends that some clines are non-adaptive because apparently independent of environmental gradients. Here again we just do not know, and he admits that probably some selective factors are involved.

It seems only reasonable, therefore, to suggest that those characters or variation patterns that have been described as non-adaptive or random should properly be described as uninvestigated. One must not assume randomness (or selection) without proof.

Growth Inhibition in Amphibian Larvæ by 4-Amino Pteroyl Glutamic Acid (Aminopterin)

A number of workers have demonstrated the inhibition of growth in the rat and mouse[1,2], bacteria[3-5], and in the chick[6-8] by means of folic acid antagonists. Seeger *et al.*[9] have shown that 4-amino pteroyl glutamic acid is a powerful antagonist of folic acid by the *Streptococcus faecalis* R. test, and its toxicity in mammals has been well established.

Karnofsky *et al.*[7] demonstrated quite conclusively that 4-amino pteroyl glutamic acid, as an analogue of folic acid, has the ability to inhibit growth in the chick, and the question arose as to whether this reaction could be found in a cold-blooded vertebrate as well. In this preliminary report, the growth inhibition of amphibian larvæ by 4-amino pteroyl glutamic acid is indicated, particularly in the growth phases in the middle and late larvæ. Studies on inhibition in early development, effects on embryogenesis, and possible reversal effects are to be presented elsewhere at a later date.

Adult *Rana pipiens* were ovulated by pituitary induction and the eggs stripped and fertilized. At the two-cell stage, the eggs were divided into two groups: group *B*, in which the tertiary membranes were left intact, and group *C*, in which the tertiary membranes were removed. Group *A*, serving as controls, consisted of two further series, one with membranes intact, the other with membranes removed from the eggs. The eggs were allowed to develop in pond water at a temperature of 18° ± 0·5° C. Groups *B* and *C* received daily doses of 4-amino pteroyl glutamic acid (aminopterin) (Lab. No. 7-9332 furnished through the courtesy of Dr. E. L. R. Stokstad, Lederle Laboratories Division, American Cyanamid Corp., Pearl River, N.Y.) as follows: 1,000, 500, 100 and 10 µgm. per 100 c.c. of pond water in a single bowl. Because the antagonist forms degradation products after twenty-four hours, daily changes were made of the liquid contents of the bowls in which the animals were kept.

Table 1. EFFECT OF AMINOPTERIN ON THE DEVELOPMENT OF LATE ANURAN LARVÆ WITH MEMBRANES INTACT.

Each observation is the mean for 3–5 larvæ; temperature of habitat bowls containing larvæ, 18° ± 0·5° C.

Stage (Shumway)	Micrograms of aminopterin 1,000	500	100	10	0 (Controls)
	(All measurements expressed in mm.)				
19	6·0	5·9	5 9	5·3	6·0
22	9·9	8·8	8·2	7·8	8 6
24	11·4	10 8	10·8	10·3	10 6
24–25	11·0	10·8	12·0	11·1	12 0
25	11·6	10·6	12·3	11·9	13·1
25+	12·3	10·4	13 4	12·0	14 7

In series *B* (Table 1), the most marked inhibition appears to occur immediately following stages 21–22[9], at which time the mouth is open and the larvæ begin actual feeding. A dosage of 1,000 µgm. is not a lethal dose for anuran embryos and, further, it does not appear to produce such marked inhibition as, for example, 500 µgm. does for this series.

Table 2. EFFECT OF AMINOPTERIN ON THE DEVELOPMENT OF LATE ANURAN LARVÆ WITH MEMBRANES REMOVED.

Each observation is the mean for 3–5 larvæ; temperature of habitat bowls containing larvæ, 18° ± 0·5° C.

Stage (Shumway)	Micrograms of aminopterin 1,000	500	100	10	0 (Controls)
	(All measurements expressed in mm.)				
19	5·5	5·6	5 1	6·1	5·3
22	8·8	8·5	7·5	7 2	8·1
24	10 2	10·5	9·1	10 4	11·4
24–25	10·2	10·5	10·5	11·9	13·3
25	10·2	11·6	10·5	12·4	14·8
25+	dead	dead	9 6	12·0	15·3

Results for series *C* are presented in Table 2. It is presumed that larvæ in this group were in more direct contact with the actions of the antagonist, as the highly selective factors effective within the outer membranes are discounted, since the greater portion of the tertiary membranes were removed. Here both 1,000 µgm. and 500 µgm. represent a lethal dosage for the larvæ. Prior to death, the greatest inhibition of growth occurred in animals given 1,000 µgm.

From these results it appears that 4-amino pteroyl glutamic acid has an inhibiting effect upon the growth of middle and late *R. pipiens* larvæ. The mode of action of this inhibition is not yet known. In the higher vertebrates, 4-amino pteroyl glutamic acid is not an ideal metabolic inhibitor, as a reversal effect cannot always be obtained by administration of folic acid[8,10]. Also, it is difficult to say whether the inhibition of growth observed in experiments employing folic acid antagonists is due to a general interference with the growth of the larvæ or injury to a specific tissue leading to retardation as a whole. The work now in progress is designed to investigate this matter. There are indications that the antagonist interferes with the more actively growing areas, those tissues which grow more rapidly being most affected. The abnormalities produced by graded concentrations of 4-amino pteroyl glutamic acid in the early frog embryo are rather non-specific and have been produced by a variety of experimental procedures. All are believed to interfere with the energy expenditure of the embryo, causing failures in gastrulation, neuralation, as well as in other phases of growth. It is quite likely that the action of the antagonist in this case is of a similar nature. Experiments are now in progress which consider this premise.

A Micro-method for the Examination of the Biochemical Activities of Micro-organisms

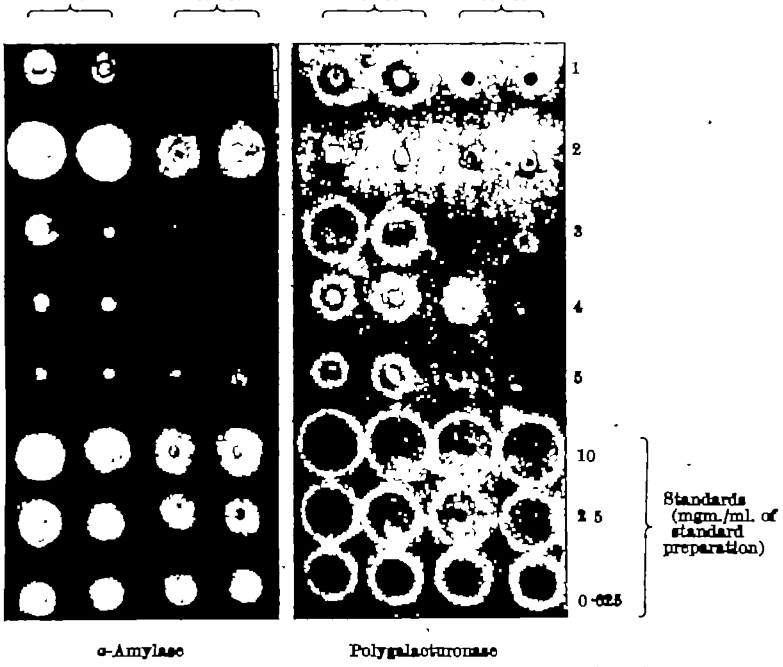
THE large-scale screening of cultures of micro-organisms for biochemical activities is nowadays frequently designed to select organisms which are effective in submerged culture[1]. We have recently developed a technique for the examination of hundreds of cultures for their suitability for surface culture, with particular reference to enzyme formation.

The method consists in growing the organism in a small cylinder containing 0·1 ml. of an agar medium, which is added aseptically from a hot-water jacketed micro-burette. The cylinders rest on a thin polyvinyl chloride sheet in a Petri dish, containing up to 40 cylinders. The latter, usually porcelain or glass, are conveniently sterilized in glass columns prior to filling. With two operators, 500 cylinders can be filled in an hour. Using spore suspensions, five fungi have been inoculated in one dish, with no cross-infection. Incubation in a humidity chamber is necessary, to prevent drying out of the medium. When the mycelial mat is formed, little drying is observed after ten days incubation, and the growth of twenty different fungi was quite typical and sporulation was not retarded.

For estimating the metabolic products formed, a modification of the agar-plate diffusion technique has been used[1,2]. The plugs of agar inside the cylinders are transferred to a glass sheet by extrusion with a glass rod. For estimating enzyme activity, a suitably buffered 1·5 per cent agar solution containing the substrate is poured on to the plate at 48–50° C. This ensures that a perfect seal is formed around each plug. It is necessary to include salicylanilide in the assay medium, to prevent further growth during the assay. The glass sheet is incubated for twenty-four hours and developed with a suitable reagent. In a typical experiment, five fungi were examined for α-amylase and polygalacturonase, sample plugs being removed and assayed each day for ten days. In the accompanying photograph, two typical plates, for polygalacturonase and α-amylase, are shown with zones, representing a day's samples, and dilutions of a standard enzyme preparation to allow calculation of the enzyme concentrations in the unknowns. This photograph shows that in the case of *Aspergillus flavus oryzae* (sp.) large amounts of α-amylase are produced, but no polygalacturonase; with *Penicillium chrysogenum* the reverse is apparent.

Other products can be estimated using plain agar plates, and after diffusion development with a suitable reagent, for example, kojic acid, developed with ferric chloride to give red zones around the plug; antibiotics can be assayed by the usual methods. The technique is being used successfully for the screening of cultures of micro-fungi, and by using purified agar and nutrients, the effect of nitrogen source, growth factors, etc., on the biochemical activities of a culture can be readily studied. Full experimental details will be published elsewhere.

ASSAY OF DUPLICATE THREE-DAY OLD CULTURES OF MICRO-FUNGI, GROWN AT 25° AND 37° C., FOR α-AMYLASE AND POLYGALACTURONASE



Organisms: (1) *Aspergillus foetidus* (n.sp.); (2) *Aspergillus flavus-oryzae*; (3) *Botrytis cinerea*; (4) *Penicillium chrysogenum*, Q.176; (5) *Syncephalastrum cinereum*.

Unicellular Algæ as a Source of Food

SUPPLIES of food are not enough to give the present world population an adequate diet, and population is increasing more rapidly than the output of agriculture. In 1948, Dr. F. N. Woodward (then at the British Commonwealth Scientific Office, Washington) reported that some American scientific workers thought the problem could only be solved by devising non-agricultural methods for producing proteins, fats, carbohydrates, etc. One of the American suggestions was that unicellular green algæ, suitably cultured, might give much higher yields per acre than conventional agricultural crops. Among the algæ suggested were species of *Chlorella* and *Scenedesmus*.

Calculations based on available data, from researches into photosynthesis in which *Chlorella* is widely used as the experimental subject, suggested that it was theoretically feasible to obtain much higher yields per acre from *Chlorella* than from agricultural crops. (One of the assumptions made was that the alga could be grown in shallow ponds.) Experimental work was therefore started at Jealott's Hill to obtain more information. Much remains to be done before the economic possibilities can be accurately assessed; but it is hoped that the present account of the position we have now reached may be of help to others engaged in similar research.

The growth and composition of unicellular algæ are influenced by many factors, most of which are interrelated. Hence, determination of the optimum conditions for the mass culture of these organisms would involve considerable time and effort. Our approach has therefore been somewhat arbitrary, the aim being to devise a technique which would give reasonably high yields of a product with a tolerably constant composition.

This work has been conducted with *Chlorella vulgaris* var. *viridis*; but it is recognized that this may not be the most suitable alga. The diameters of the cells of the strain used in these experiments ranged from 3 to 10 microns. *Chlorella* multiplies by binary fission, and there are four distinct stages in the growth-cycle: a lag phase, an exponential phase, an approximately linear phase, when growth is somewhat less than in the exponential phase, and finally a stationary phase.

The size of the inoculum used in all the cultures described here was equivalent to 5 mgm. of dry matter per litre. The yield of dry matter was considerably increased by eliminating the initial lag phase in growth. This was done by inoculating with cells that were in the exponential growth phase.

At the beginning of these investigations, a nutrient medium recommended by Winokur[1] was used; but it was found that when nitrate nitrogen was replaced by ammoniacal nitrogen, higher yields of dry matter were obtained, and that when ammonium nitrate was used the organism preferentially absorbed the ammonium ion. Accordingly, in all subsequent experiments ammoniacal nitrogen was used. The *p*H of the medium was initially adjusted to 6·0, and throughout the incubation period it was readjusted twice daily. The optimum temperature is about 25° C., growth being much poorer at 20° C. and 30° C. In all experiments carbon dioxide has been supplied, chiefly for convenience, as a 5 per cent carbon dioxide – 95 per cent air mixture. Only 15 per cent of the carbon dioxide supplied escaped to the atmosphere, that is, about 85 per cent was used by the organism.

The cultures were illuminated by 'daylight' fluorescent tubes. Very good growth was obtained at 1,300 foot-candles. It was appreciated that artificial illumination might be quite uneconomic, but it was essential to have a constant light source when other factors were being studied. Tests showed that if the cultures were illuminated for 8 hr. and kept in the dark for 16 hr. each day, yield per unit of light supplied was as high as with continuous illumination; that is, the cells did not appear to go off exponential growth in the dark period. It is therefore theoretically possible to use daylight and get high yields. In southern England, illumination (not direct sunlight) averages about 1,250 foot-candles for 8 hr. a day for six months of the year and about 750 foot-candles for another two months. In lower latitudes, conditions might be more favourable.

Agitation was found necessary for maximum yields. In our experiments in tubes, an intermittent air 'blast' was used.

In the earlier experiments, the organism was cultured in flasks and in narrow cylinders. In a later experiment it was cultured in a battery of tubes 4½ ft. long × 2½ in. diameter with continuous lighting (1,300 foot-candles). When harvesting every sixth day over a period of months, the average yield was 1·9 gm. dry matter/litre/6 days. Later, a batch process was run in these tubes, the idea being to maintain a fairly dense population growing exponentially. Each day, three-quarters of the liquid in each tube was run off, the cells removed and the liquor, suitably adjusted with nutrient and water, returned. The average yield per litre harvested was 0·7 gm./day.

Harvesting by ordinary filtration proved difficult, as the cells bed down tightly; but centrifuging is quite satisfactory. The product was freeze-dried and its composition has been fairly constant; namely, 8 per cent nitrogen (47 per cent 'true' protein), 1–5 per cent ether extract and 7·5 per cent ash. It is deep green in colour and contains more than 1,200 p.p.m. of β-carotene.

The amount of 'fat' extracted by ether alone was between 1 and 5 per cent; but ether extraction after dilute acid hydrolysis or straight methanol extraction removed about 20–25 per cent of the material. The nature of this is being investigated, as are the amino-acid content of the protein and the constituents of the 'carbohydrate' fraction.

The product might be used as food for animals or even humans, or as a substrate for growing other organisms. Through the kind co-operation of Dr. Kathleen M. Henry, feeding tests on rats were conducted at the National Institute for Research in Dairying. The diet contained 17 per cent freeze-dried *Chlorella* cells, and the 'protein efficiency ratio', though less than that of skimmed milk, was significantly higher than that of dried brewers' yeast or groundnut meal.

Our work is being continued and will be reported in detail elsewhere at a later date.

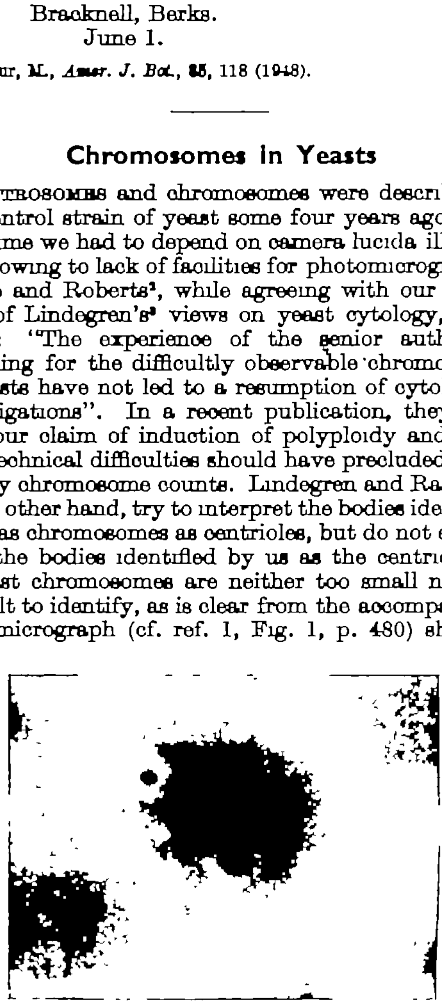
Chromosomes in Yeasts

CENTROSOMES and chromosomes were described in our control strain of yeast some four years ago[1]. At that time we had to depend on camera lucida illustrations, owing to lack of facilities for photomicrography. Winge and Roberts[2], while agreeing with our criticisms of Lindegren's[3] views on yeast cytology, comment: "The experience of the senior author in searching for the difficultly observable chromosomes in yeasts have not led to a resumption of cytological investigations". In a recent publication, they[4] dispute our claim of induction of polyploidy and state that technical difficulties should have precluded satisfactory chromosome counts. Lindegren and Rafalko[5], on the other hand, try to interpret the bodies identified by us as chromosomes as centrioles, but do not extend it to the bodies identified by us as the centrioles.

Yeast chromosomes are neither too small nor too difficult to identify, as is clear from the accompanying photomicrograph (cf. ref. 1, Fig. 1, p. 480) showing



Photograph from a smear of an aerobic liquid culture fixed in Carnoy and stained with iron hæmatoxylin. × c. 5,750 an early metaphase condition. The two chromosomes are orientated on a spindle at the poles of which can be seen the centrioles with the centrospheres.

Photomicrographs illustrating induction of polyploidy and the cytological behaviour of such induced autotetraploids are awaiting publication elsewhere[6].

Recent Climatic Variations in Indonesia

IN the past few years, interest in recent climatic changes has been growing. Especially in moderate and high latitudes of the northern hemisphere, climatic variations for several decades have been studied. The most striking phenomenon is the rise in temperature, especially that of winter temperatures, up to about 1940[1]. Petterssen[1] showed that this climatic change in moderate and high northern latitudes is connected with a variation of circulation. A similar rise in temperature, although much less marked, has occurred in certain equatorial regions[2]; further, it was found that about the year 1921, or at any rate between 1920 and 1939, the rate of rise of temperature increased rather suddenly.

To show a change in circulation with the aid of pressure and wind observations is much more difficult for equatorial regions than elsewhere, due to the smaller differences in pressure and wind. It seems to be possible, however, to draw certain conclusions on the climatic variation in equatorial regions by considering the precipitation records of Indonesia, where regular measurements of this climatological element have been taken from 1879 onward. In order to omit, so far as possible, the influence of the normal variation in sunspot numbers, we took overlapping eleven-year totals of the amounts of precipitation for West Java, Central Java, East Java (each being a mean of twenty representative stations), and for about thirty stations in the other islands of Indonesia.

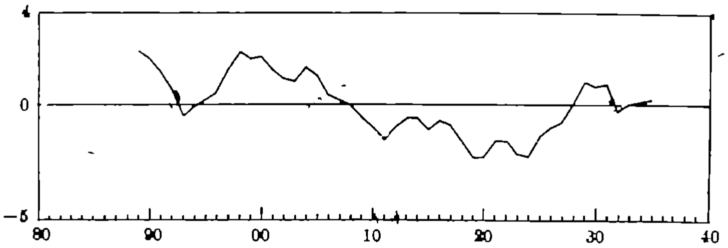

Fig. 2. Overlapping 11-year totals for the air pressure in Hongkong

Considering these eleven-year totals, it appeared possible to distinguish two groups, each of about ten stations (including the three provinces of Java), the groups showing an anti-parallel course. In the first group, the eleven-year totals for rainfall show a maximum between 1920 and 1930, whereas the stations of the second group show a minimum during this period, which is the very period during which the rate of temperature rise increased. The stations of the first group are crowded along the equator, whereas those of the second group consist of stations situated in the southern hemisphere between, say, lat. 2° and 10° S.

The difference between the maximum and the minimum eleven-year totals for precipitation may in each group amount to as much as 20 per cent of the mean eleven-year total itself. This suggests that we have to deal with an important climatic fluctuation. In Fig. 1, Pontianak, situated on the equator, is an example of the first group, whereas West Java belongs to the second group. The correlation coefficient calculated from the 11-year totals of the precipitation at Pontianak and in West Java over the period 1879–1940 is -0.75. It appears from Fig. 1, however, that during the first ten years of this period the relation existing between the two precipitations is different from that during the remainder of that period.

If we confine ourselves to the eleven-year totals from 1889 onward, we find r to be -0.89, with a standard error of 0·03. It seems clear from these figures, and also from their graphical representation, that we are dealing here with a strong interdependence between the climatic variations in Pontianak and those in West Java. This interdependence may be the outcome of the southward displacement of the 'intertropic zone of convergence' in the autumn and winter of the northern hemisphere, and of its northward displacement in the spring; for these displacements manifest themselves in the amounts of

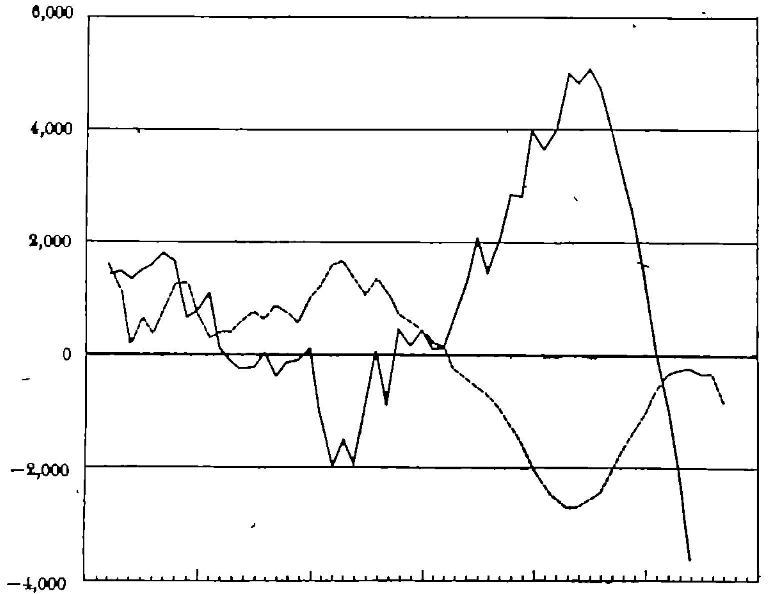

Fig. 1. Overlapping 11-year total for the precipitation in Pontianak (full line) and West Java (broken line)

precipitation, the rainfall being especially abundant during the passing of the convergence.

To show further proof of this influence of the intertropic zone of convergence, the 11-year totals for the pressure at Hongkong are given in Fig. 2. This quantity may be regarded as being representative of the intensity of the Siberian pressure maximum, and therefore to be determining very largely the convergence displacements over Indonesia. The connexion already follows from the figures. High pressure at Hongkong is accompanied by a maximum of precipitation in West Java, and a minimum at Pontianak. The correlation coefficient between the 11-year totals for the pressure at Hongkong and the 11-year totals for the precipitation in West Java is + 0·55 with a standard error of 0·10.

These results show clearly that variations of circulation occur not only in moderate latitudes, but also in the tropics.

We intend to discuss elsewhere in some detail the problem of recent climatic variations in Indonesia.

The Lithium-7 Nucleus

OBSERVATIONS by Rose and Wilson[1] in the reaction $^{10}\mathrm{B}(n,\alpha')^{7*}\mathrm{Li}(\gamma)^{7}\mathrm{Li}$ and by Littauer[2] in $^{7}\mathrm{Li}(p,p')^{7*}\mathrm{Li}(\gamma)^{7}\mathrm{Li}$ have shown that the 480-keV. gamma ray is emitted isotropically in these reactions. In the former experiment the yield of radiation was measured relative to the direction of emission of the short-range alpha particle. In the latter case it was determined with respect to the incident proton. These observations constitute strong evidence that the spin of the 480-keV. state is $\frac{1}{2}$, although in both cases the lack of a correlation could arise from other special circumstances. Accordingly, we have looked for a correlation between the short-range proton and the gamma-ray in the $^{6}\mathrm{Li}(d,p')^{7*}\mathrm{Li}(\gamma)^{7}\mathrm{Li}$ reaction.

A thin target of lithium-6, prepared in a mass spectrograph[3] and maintained constantly under vacuum, was bombarded with 0·80 MeV. deuterons from an electrostatic generator. The protons and the gamma rays from the reaction were detected with suitable scintillation counters, and successive proton-gamma emissions were observed by operating the counters in coincidence. The particle detector was placed so as to observe protons emitted in the direction of the incident beam. The gamma-ray counter was operated at angles varying between 35° and 145°. Despite the relatively pure lithium-6 target and considerable shielding, the accidental coincidence-rate was high, with resolving times of somewhat more than 10^{-8} sec., when beam currents were used large enough to make the rate of detection of real coincidences reasonable. Provision was made therefore for constantly monitoring the accidental coincidence-rate. This was desirable also because of fluctuations in the counting-rate arising from the unsteady source[4].

The reaction itself was monitored by observing the single-channel counting-rate of the fixed proton counter, and also by means of a beam current integrator. The single-channel counting-rate from the gamma-ray counter was observed but was not a true measure of the yield of radiation of the reaction under study, because of the presence of other gamma-rays resulting from the deuteron bombardment of lithium-6 and target impurities.

The proton-gamma coincidence-rate was measured at nine settings of the gamma counter. Upward of 2,000 coincidences were obtained at each angle. The coincidence-rate per proton, corrected for small variations in the distance of the gamma counter, varied in a random fashion within the statistical limits of the measurements, which were between 5 and 10 per cent. A least-square analysis of these data into a cosine series gives a coefficient of $\cos^2\theta$ which is less than 3 per cent of the isotropic term. Because of the low recoil velocity of the lithium-7 nucleus in this experimental arrangement ($9\times10^{-3}\,c$), the Doppler effect produces a negligible correction. A check was made on the amount of gamma-ray scattering present and the reality of the observed coincidences by placing lead absorbers in front of the gamma-ray detector at several gamma-angles. The results verified the nature of the coincidences, and indicated that the effects of scattering were small and not noticeably dependent on the angle.

This lithium-6 reaction differs from the boron-10 reaction investigated by Rose and Wilson[1], in that the compound nucleus beryllium-8 is not formed entirely by *s*-wave capture[5]. In the present experimental arrangement, however, the complexity of the correlation will be determined primarily by the properties of the excited state in lithium-7 and the subsequent radiation. The failure to detect a correlation in this experiment, therefore, is consistent with the assignment of $I = \frac{1}{2}$ to the 480-keV. state. Additional experimental details and a theoretical discussion will appear elsewhere.

31-keV. Excited State of Aluminium-28

A RECENT accurate magnetic analysis of the proton groups from the reaction $^{27}\mathrm{Al}(d,p)^{28}\mathrm{Al}$ by Strait and his collaborators[1] showed the presence of an excited state in the residual nucleus of aluminium-28 at 31 ± 2 keV.

The existence of such a low-lying level in a light nucleus is of considerable interest. Predictions of the positions of the lowest nuclear levels have been made by considering the rotation of the nucleus as a whole[2,3], and the excitation energies thus calculated show reasonable agreement with the levels previously experimentally determined. However, the lowest rotational level for the aluminium-28 nucleus would be expected to have an excitation energy above 100 keV., and a level at 31 keV. could not be a simple rotational level. It is also unlikely that such a level could be explained on the basis of the nuclear shell model recently discussed by Mayer[4] as a splitting of the ground state due to spin-orbit interaction. In this connexion a knowledge of the multipole order of any gamma-ray transition between this level and the ground state would be of value.

In view of the particular interest of this level, a search has been made for gamma-radiation resulting from its de-excitation. An aluminium target was bombarded with deuterons with an energy of 700 keV. The radiation was detected at 90° to the deuteron beam with a proportional counter. The counter, 4 in. in diameter, was fitted with 'field tubes'[5] to eliminate end effects, and filled with argon and methane to partial pressures of 3 atmospheres and 15 cm. respectively. The counter was screened with 3 in. of lead, and the β-particles from the decay of aluminium-28 and nitrogen-13 (produced from carbon contamination of the target) were prevented from reaching the counter by polythene absorbers and the field of a strong permanent magnet.

Radiation of an energy of 31·4 ± 1·0 keV. was detected and presumed to be due to the de-excitation of the 31-keV. level in aluminium-28. The peak counting-rate was about one quarter the background rate. This background was due to gamma-radiation and neutrons both from the target and from reactions produced by that part of the beam which struck the walls of the resolving chamber. The background not originating at the target was variable, and to minimize this variation it was necessary to keep the beam current and focus particularly steady during counts. Successive counts were made with aluminium and lead absorbers of equal surface density at each setting of the pulse analyser. The difference between these pairs of counts is plotted in the accompanying graph as a function of pulse amplitude. The spectrum of the K X-rays of tin is also shown. The energy of the gamma-ray was determined by comparison with these X-rays and those of barium, produced by proton bombardment of targets of metallic tin and barium chloride. Absorption measurements of the gamma-radiation were also made and were consistent with the energy thus determined.

The radiation was also detected by a scintillation method. A thallium-activated sodium iodide crystal 1 cm. square and 1 mm. thick was mounted on an *E.M.I.* type 5311 photomultiplier and screened with 3 in. of lead. The β-particles were absorbed with polythene. Although the background was less than that experienced with the counter, the resolution of the crystal was inferior and the counter was, therefore, used for determining the energy of the gamma-ray.

From the calculated efficiency of the counter and on the assumption that the radiation is isotropic, the yield from a thick aluminium target at a bombarding energy of 700 keV. was estimated to be 1·1 ± 0·5 × 10^8 γ per microcoulomb.

The low-energy electrons from this reaction have been examined with a 180° magnetic spectrometer. No internal conversion electrons corresponding to the 31-keV. gamma-ray have been detected: from the efficiency of the spectrometer it is estimated that the internal conversion coefficient α_K is less than 2. Such a value suggests that the transition to the ground state is electric dipole. A more precise measurement is to be made.

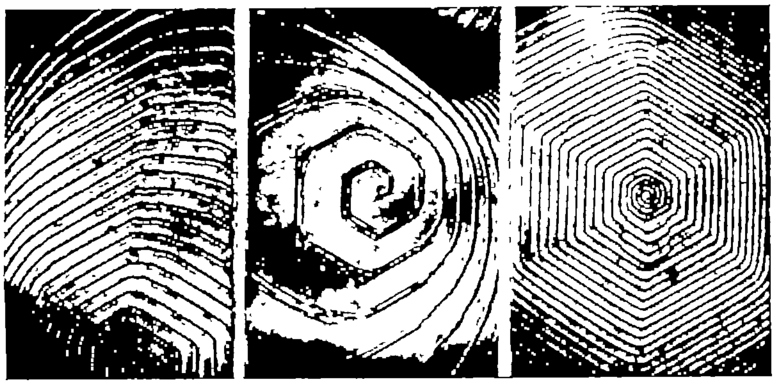
Growth Spirals on Carborundum Crystals

The observation of growth spirals on carborundum crystals has been reported earlier[1]. These growth spirals can be divided into two classes: (1) those in which the step-height between the successive edges of the spiral is equal to the height of a unit cell; and (2) those in which the step-height is a multiple of it. The latter type of multi-stepped spiral will result from a dislocation the strength of which is a multiple of the repetition period, the Burger's vector being a multiple of the height of the unit cell. Such spirals have been found to originate at a large hole (see Fig. 2); they have a much higher optical visibility because of the relatively large step-height, being therefore easily observed with a microscope using bright-field illumination. Of the numerous spirals of this kind seen, two typical examples are shown here. The steps of these spirals can break up into their component steps under certain conditions. In Fig. 1, showing only one half of the spiral, the various components advance together in different directions for some twelve turns, after which they break up into five or six close branches. In Fig. 2 is illustrated a case where the dissociation takes place quite near the centre and growth can be regarded as taking place from the multiple dislocations.

Carborundum[2] is a polytypic crystal. In the hexagonal types or the rhombohedral types referred to the hexagonal axes, the number of layers necessary for the arrangement to repeat itself is also the number of 'formula weights' in the unit cell. However, in the actual rhombohedral unit cell, the number of formula weights is one-third of the total number of layers included within the c-axis. The measurement of the step-height of the growth-spirals on the different types should be able to show this point.

On the hexagonal type II crystal (6H in Ramsdell's notation) the step-height measurements have already been given[1] and shown to be equal to the height of the unit cell (c = 15 A.). Further measurements of the step-height, by the application of multiple-beam interferometry on the growth spirals on the different rhombohedral types, are now reported here.

On a type I crystal (15R in Ramsdell's notation) the measured step-height is 12 ± 2 A. This is equal to one-third of the lattice parameter c of the unit cell referred to the hexagonal axes, and is in agreement within experimental error with the predicted X-ray value of a_{rh} = 13 A. of the rhombohedral cell. The visibility of this growth spiral is consistent with this measurement of step-height.



(1) (2) (3)

On a type VI crystal ($33R$ in Ramsdell's notation), the measured step-height is 28 ± 2 A., which again is very close to a_{rh} of the rhombohedral cell, and within experimental error is identical with it.

Fig. 3 shows a hexagonal spiral with step-height nearly 130 A., and it may be concluded that it is one of the types with giant unit cells. If a_{rh} is indeed equal to the step-height of 130 A., then the classification is probably $159R$.

Thus, it seems established that the step-height is equal to the height of the actual unit cell. This gives another physical confirmation of the existence of the X-ray unit cell.

I wish to express my thanks to Prof. S. Tolansky for his interest in the work, and to the British Council for the award of a scholarship.

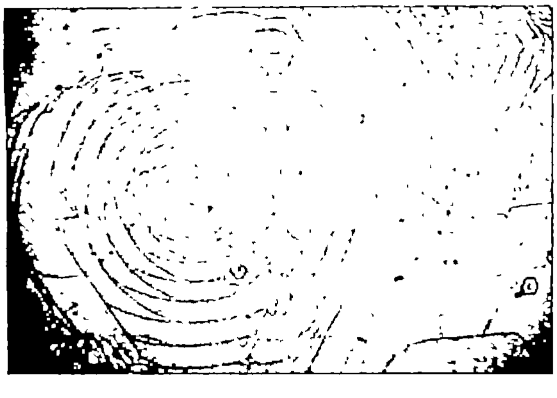
Growth Mechanism of Carborundum Crystals

GROWTH spirals, as predicted by F. C. Frank's theory[1] on crystal growth, have been observed on the c(0001) faces of carborundum by Ajit Ram Verma[2] and by S. Amelinckx[3]. The steps between successive turns, as stated by Frank, are exactly one unit cell high. This seems, in fact, to be true in many cases, although steps of several unit cells high are not exceptions.



We now have evidence that layers thinner than one unit cell are formed in certain circumstances.

The photograph reproduced herewith shows a growth pattern on a c(0001) face of a carborundum crystal. The technique of observation was the same as the one used previously. By means of Weissenberg photographs about an α-axis, we found the crystal to be of the type $6H$ (formerly type II)[4]. The structure of this type of carborundum can be considered as being made up of superimposed three-layered lamellæ, each lamella rotated 180° to that immediately below it[5]. The unit cell contains two such lamellæ, and each of them has trigonal symmetry about the c-axis.

The accompanying photograph shows a double growth-spiral. The two components are generated by the same dislocation end; both have trigonal symmetry as shown by their radial growth-velocity, but their orientation differs by 180°. This shows that two successive sheets are not equivalent.

The average height of a step between successive loops of the spiral was measured by means of multiple beam interferometry[6] and found to be 7 ± 2 A., that is, the height of one three-layered lamella (or half a unit cell).

The most logical interpretation of this pattern would appear to be that these two spirals are due to the growth of each lamella separately. Consequently carborundum crystals (of type $6H$) seem to grow, at least in certain circumstances, not by unit cells but by three-layered lamellæ. Probably similar conclusions will hold for the growth of the other types of silicon carbide; they could provide a basis for the explanation of the existence of the numerous types of carborundum which are known.

A more detailed account of this work is being published elsewhere.

I am grateful to Prof. W. Dekeyser for continuous interest and encouragement. This work is part of a research scheme supported by the Centre National, Belge de Chimie Physique Moléculaire, to which I am indebted for a research fellowship. The carborundum samples were kindly provided by S.E.C.E.M.A.E.U. (Usine de la Bathie, France).

Crystal Structure of Ergine

ERGINE, $C_{16}H_{17}ON_3$, the amide of lysergic acid, is the simplest of the ergot alkaloids. It forms salts with hydrochloric and hydrobromic acids, and crystals of these were kindly put at our disposal by Prof. A. Stoll, of Basle. Both salts crystallize in elongated colourless plates, which are optically biaxial positive with the plane of the optic axes perpendicular to the *b*-axis.

Exposures were made of the (*h*0*l*), (*h*1*l*), (0*kl*) and (1*kl*) zones of both compounds with a Weissenberg camera, using copper $K\alpha$ radiation.

Oscillation photographs around the three axes were also taken. The following results were obtained from these photographs :

$B\cdot$HCl · $a = 9\cdot44° \pm 0\cdot02$ A.
$b = 5\cdot74 \pm 0\cdot01$ A.
$c = 18\cdot60 \pm 0\cdot05$ A.
$\beta = 91\cdot2°$

B HBr : $a = 9\cdot60° \pm 0\cdot02$ A.
$b = 5\cdot74 \pm 0\cdot01$ A.
$c = 13\cdot79 \pm 0\cdot05$ A.
$\beta = 91\cdot2°$

The compounds proved to be isomorphous, space group $P2_1$. The measured densities of 1·40 and 1·56 for hydrochloride and hydrobromide respectively indicated two molecules in the unit cell. The intensities of the (*h*0*l*) and (0*kl*) reflexions of both compounds were estimated visually, and corrected for the Lorentz polarization factor. The F^2-values were brought on to an absolute scale, using Wilson's method[1]. Patterson maps were prepared for both compounds along [100] and [010], using *X-RAC* (calculation on *X-RAC* under contract No. N6onr-26916, T.O. 16 with the Office of Naval Research). The co-ordinates of the halogen atoms were found from these maps.

In addition, a Patterson map was prepared, using as coefficients ($F^2{}_{B\cdot\mathrm{HBr}} - F^2{}_{B\cdot\mathrm{HCl}}$). These maps show only the vectors between atoms of weight (Br—Cl), and between these atoms and the lighter atoms. Vectors between the lighter atoms only do not appear. This Patterson map was drawn twice with its origin at each of the two halogen positions. These two drawings were superimposed and points were marked where regions of high vector density coincided[2], as is shown in Fig. 1.

Signs of the (*h*0*l*) coefficients were calculated from the halogen contributions using the isomorphous rule. Electron density maps on (010) prepared on *X-RAC* for both compounds showed the molecule clearly resolved. By successive Fourier approximations, and using the criterion of non-negativity of the background on *X-RAC*[3], the (010) projection was refined to give Fig. 2, which is essentially the same as Fig. 1.

The chemical formula proposed by Jacobs, Craig and collaborators[4], with an indole group coupled with two non-aromatic rings, is confirmed. Interpretation and refinement of an electron density map on (100) is now in progress.

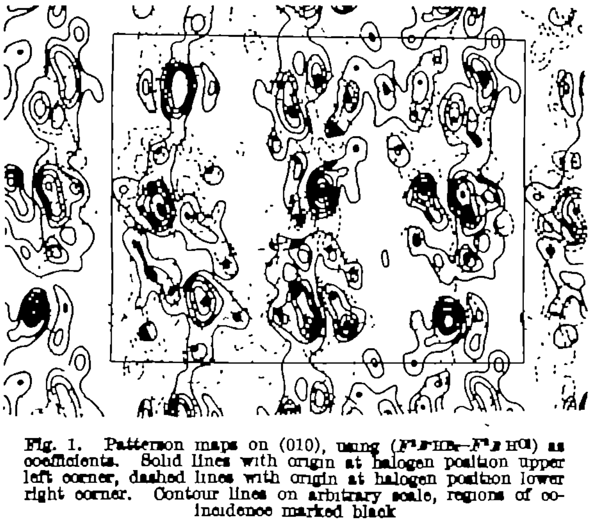

Fig. 1. Patterson maps on (010), using ($F^2{}_{B\cdot\mathrm{HBr}} - F^2{}_{B\cdot\mathrm{HCl}}$) as coefficients. Solid lines with origin at halogen position upper left corner, dashed lines with origin at halogen position lower right corner. Contour lines on arbitrary scale, regions of coincidence marked black

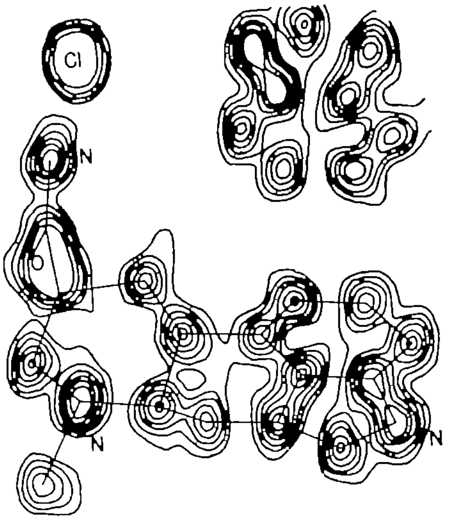

Fig. 2. Part of final electron density projected on (010) of *B* HCl, showing the molecule. Contour lines on arbitrary scale

We wish to express our gratitude to the Research Corporation, Lilly Research Laboratories, and the Office of Naval Research, for support on the programme of which this investigation is a part.

Age of Tektites

AN investigation has been made of the argon content of tektites utilizing the mass-spectrometric isotopic-dilution technique in an attempt to find a clue to the origin of these supposedly meteoric glasses[1]. Previous investigations have shown that the bubbles frequently present in tektites have a gas pressure of less than 10^{-4} atmosphere[2], and that the total argon content of the tektites is below the limits of detection of the ordinary methods of gas analysis[3]. These results show that, from the point of view of age determination of these materials by the argon method, diffusion is negligible.

Tektite samples weighing about 10 gm. each were broken into fragments having dimensions of about 3 mm. These fragments, together with a known quantity of 97·5 per cent argon-38, prepared by neutron irradiation of sodium chloride, were introduced in a vacuum into a stainless-steel system containing about 30 gm. of outgassed sodium hydroxide flux at 400° C. The gases obtained were purified by passage through cupric oxide, a liquid-air trap and a calcium furnace. Finally, the remaining gases were adsorbed on activated charcoal, transferred to a mass spectrometer and their argon isotopic composition determined.

Two experiments were made with the so-called 'gas-rich' tektites from the Philippines and one with an australite. The Philippine tektites came from a Mid-Pleistocene deposit and the australites from a 'practically recent' deposit. The K_2O content given in the literature for these types of tektites ranges between 2 and 2·8 per cent. Dr. O. Joensuu, of the Department of Geology in the University of Chicago, has kindly made a spectroscopic determination of the potassium content of our samples. We have used his results in our calculations.

The results are shown in the accompanying table. The ages obtained are based on a value of $1·33 \times 10^9$ years for the half-life of krypton-40, a value of 7·92 for the ratio of decay to calcium as compared to the decay to argon, and a value of 0·0119 per cent for the abundance of potassium-40. The amounts of argon obtained were so small as to preclude measurement of the argon-36 peak to determine whether the argon-40 was of radiogenic or atmospheric origin. Thus, to set upper limits to the ages of the tektites, we have assumed that all the argon-40 measured was radiogenic. Since experiments run without tektites present give amounts of argon-40 comparable to that obtained from the tektites, it seems probable that the actual age of the tektites is less than the ages quoted.

ARGON CONTENT AND THE AGE OF TEKTITES

	Philippinite		Australite
	1	2	3
Wt. of sample	5·66 gm.	8·80 gm.	12·27 gm.
Potassium (per cent)	1·70 ± 0·2	2·16 ± 0·2	1 99 ± 0·2
Argon-40 per gm. potassium	$0·282 \times 10^{-8}$ c.c.	$0·0403 \times 10^{-8}$ c.c.	$0·104 \times 10^{-8}$ c.c.
Argon-40 per gm. potassium expected for 2×10^9 year age	$13·7 \times 10^{-8}$ c.c.	$13·7 \times 10^{-8}$ c.c.	$13·7 \times 10^{-8}$ c.c.
Max. age (yr.)	$< 73 \times 10^6$	$< 10 \times 10^6$	$< 32 \times 10^6$

The results show that the tektites are definitely much younger than the solar system, and also that they are much younger than the ordinary meteorites which have been dated by Paneth by means of their helium content[5].

We wish to express our thanks to Dr. Otley Beyer, Manila, Philippines, for supplying philippinites from Santa Mesa Site, Rizal Province, and to Sir Kerr Grant, University of Adelaide, and to the Museum of South Australia for supplying the australites used in this investigation.

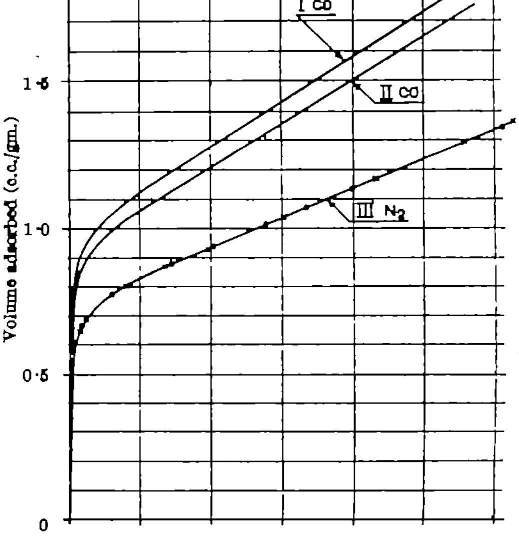
Influence of a Chemisorbed Film on Subsequent Physical Adsorption Processes

Stone and Tiley[1] have reported that the presence of a chemisorbed film of carbon monoxide reduces the low-temperature physical adsorption of krypton on a copper oxide catalyst. This observation is of particular interest, because the accepted method[2] of estimating the area of free metal in a mixed surface involves the assumptions that, at low temperatures, carbon monoxide is initially chemisorbed only on the metal surface, and afterwards physically adsorbed over the whole surface; and that the chemisorbed layer and the bare non-metallic surface have the same adsorption characteristics.

The experimental results shown in the accompanying graph were obtained with an alkali-promoted iron catalyst (as used for the Fischer–Tropsch synthesis), reduced at 450° C. in hydrogen, and degassed at 450° C. for two hours. Similar curves were obtained for two other preparations of the same type of catalyst. The sequence of operations was: (*a*) adsorption of nitrogen at – 195° C. (curve III, ⊙); (*b*) evacuation at 450° C. for half an hour, the evacuation proceeding as the temperature was increased; (*c*) adsorption of carbon monoxide at – 195° C. (curve I); (*d*) desorption of carbon monoxide at – 78° C. for half an hour, at a pressure of 10^{-4} mm. of mercury; (*e*) adsorption of carbon monoxide at – 195° C. (curve II); (*f*) desorption of carbon monoxide exactly as in (*d*); (*g*) adsorption of nitrogen at – 195° C. (curve III, ×).

The presence on the catalyst surface of an amount of strongly chemisorbed carbon monoxide corresponding to the difference between curves I and II is therefore without effect on the subsequent physical adsorption of nitrogen. For the three samples of catalyst tested, the fractions of the surface covered by chemisorbed carbon monoxide were 6·5, 11·6 and 21·5 per cent; in each case the presence of the chemisorbed layer had no effect on the subsequent adsorption of nitrogen.

A possible explanation of the curves in the graph, and of the difference between these observations and



those of Stone and Tiley, is that two different 'chemisorbed' states are involved. In one case the adsorbed molecule may be completely incorporated in the surface with loss of its individual characteristics, so that the perturbation of the original averaged surface field may not be sufficient to have any appreciable influence at the distances of purely physical attraction. It is this type of chemisorption which may be expected in the case of carbon monoxide to occur on clean metallic areas at fairly low coverages, and is represented by the difference between curves I and II. In the second case, the adsorbed molecule may remain distinct from the surface, to which it may be attached by a weak semi-polar bond, and so retain its individual character. In this case the adsorbed molecule behaves as a fresh adsorption centre, the potential at which will certainly differ from the original. This type of carbon monoxide adsorption will probably take place at high coverages on metallic surfaces, and at all coverages on oxides, carbides[3] and nitrides; it approximates to the difference between curves II and III.

A detailed experimental and theoretical investigation is in progress.

This work forms part of the programme of the Fuel Research Board and is published by permission of the director of fuel research, Dr. A. Parker.

A. S. Joy
T. A. Dorling

Fuel Research Station,
Greenwich,
London, S.E.10.
July 3.

[1] Stone and Tiley, *Nature*, 167, 654 (1951).

[2] Emmett and Brunauer, *J. Amer. Chem. Soc.*, 59, 1553 (1937).

[3] Podgurski, Kummer, De Witt and Emmett, *J. Amer. Chem. Soc.*, 72, 5382 (1950).

The results of Joy and Dorling are not altogether surprising, and their suggested explanation is generally in agreement with our views. There are, however, two points of interest.

First, it does not seem in accord with the reported heats of adsorption to refer to carbon monoxide on an iron catalyst as being "strongly chemisorbed" in contrast to the "weak" chemisorption on cuprous oxide. The initial heat of carbon monoxide on iron is approximately 25 k.cal./mole[1], whereas on cuprous oxide it is 21 k.cal./mole[2]. Moreover, after carbon monoxide adsorption at 20° C., prior to the krypton adsorption, we evacuated at a pressure of less than 10^{-4} mm. of mercury for 1 hour at room temperature, thus removing all gas adsorbed with a heat less than 18 k.cal., whereas Joy and Dorling pump off at − 78° C., removing only the gas with a heat less than 12 k.cal. (These are only approximate heat values.) The question of strength of the chemisorbed bond is therefore not immediately significant.

The difference between these two cases surely lies in the nature of the chemisorbed state and its relationship to the nature of the substrate. In so far as carbon monoxide is held on a metallic surface by a form of bonding which is essentially metallic, then the chemisorbed film may be considered as extending the surface of the metal, and no profound modification of the van der Waals adsorption potential occurs. With carbon monoxide on cuprous oxide, the adsorbate molecule is held by a covalent bond to a (largely) ionic surface, with a consequent increase in adsorption potential. It should be noted, however, that on certain metallic oxides carbon monoxide is adsorbed irreversibly, and Garner[3] has suggested that it is then incorporated into the surface as a carbonate ion ($CO_3^=$). In such cases, it seems probable that the physical adsorption characteristics are not so markedly changed, and experimental investigation is proceeding on these lines.

Since our last communication, Mr. Reeves, in this laboratory, has repeated the work, using nitrogen instead of krypton, and a similar modification of the isotherm has been observed. It is felt that in our initial discussion we tended to over-emphasize the significance of E_L, the heat of liquefaction. In order to cause a drop in the apparent value of V_m, it is not theoretically necessary that $E_1' < E_L$ but only that E_1' (heat of adsorption on the chemisorbed film) should differ considerably from E_l (heat of adsorption on the bare surface). The 'dual surface' adsorption theory of Walker and Zettlemoyer[4], in which they discuss hypothetical composite isotherms obtained from two surfaces with differing values of the Brunauer–Emmett–Teller parameter *c*, is of considerable interest in this connexion.

Application of an Incomplete Block Design to the Assessment of Quality in Cacao

During the course of recent work at the West African Cacao Research Institute, it became necessary to evaluate the products of small-scale fermentations of different types of cacao. Hitherto, samples have been judged for degree of fermentation on the appearance in longitudinal section and condition of testa. These criteria have not been sufficiently discriminating, especially in laboratory fermentation work[1], where in some instances different cacao types have given similar percentages to fully fermented beans.

An attempt has therefore been made to form a local 'taste panel' for assessment of the chocolate flavour of liquors prepared by a standard procedure recommended by the British Food Manufacturing Industries Research Association (Cocoa Panel)[2]. This consists essentially of pre-heating fermented beans at 95–100° C. for one hour before roasting them in a glass-jacketed tube placed in a glycerine bath at 148° C. for 55–60 min., depending on the state of division of the beans. The only difference from the method as recommended is that no sugar has been added to the liquors.

Preliminary work showed that with randomized blocks and 'taster Latin square' designs, panel members had to taste several samples per session, with consequent deterioration in taste perception. A method was sought which would be statistically sound and which required the tasting of only two samples on any one occasion. A given set of samples was arranged in pairs, each sample being matched against every other sample by each taster. Scoring was by pair differences, each taster being asked to distribute ten points between the two samples under test; for example, if the samples were of equal value five points were allotted to each, the pair difference here being zero. The order of tasting was at random, as was the distribution of the pairs to each taster. The subsequent statistical analysis follows the model laid down by Yates[3].

During the first series, six samples were examined by a panel of six tasters, and the analysis of variance takes the following form, in terms of pair difference throughout:

Table 1

Factor	Degrees of freedom	Sums of squares	Mean square	Variance ratio (F)
Samples	5	88·03	17·61	2·652*
Error	85	563·97	6·64	
Total	90	652·00		

* Significant effect $P < 0\cdot05$

If the samples are A, B, C, etc., the 'sample' sum of squares is derived from the expression $\frac{1}{st}(T'^{2}_{A} + T'^{2}_{B} + T'^{2}_{C} \ldots + T'^{2}_{F})$. Each of the totals T'_A, T'_B, is the sum of pair differences, no correction for the mean being required, where s is the number of samples, t is the number of tasters and the totals T'_A, etc., are derived from a table of the form shown as Table 2.

Table 2

	—	$S(B–A)$	$S(C–A)$	……	……	……
	$S(A–B)$	—	$S(C–B$	……	……	……
	$S(A–C)$	$S(B–C)$	—	……	……	……
	$S(A–D)$	$S(B–D)$	$S(C–D)$	—	……	……
	$S(A–E)$	……	……	……	—	……
	$S(A–F)$	……	……	……	……	—
Totals	T'_A	T'_B	T'_C	T'_D	T'_E	T'_F

Mean sample effects are given by $\frac{1}{st}T'_A$, $\frac{1}{st}T'_B$, etc., and these may be presented as mean scores by the addition of the general mean, that is, 5. The standard error of the difference between these values is:

$$\sqrt{\frac{2 \times \text{error mean square}}{st}}.$$

In the first series, bean samples from West African Amelonado, Gold Coast selection $E1$ and Upper Amazon selection $T60$ (Parinari × Nanay) were sorted into fully fermented and insufficiently fermented lots, the lack of 'nibbing' and presence of purple pigments being the criteria of insufficient fermentation. The bulk samples from which these were drawn were obtained from basket fermentations containing 40 lb. wet beans[4]. In the second series, unsorted beans of West African Amelonado and $T60$ were each roasted for 50, 60 and 70 min., and the results are summarized in Table 3 as mean scores.

From these results, it appeared to the local panel that the quality was not affected by the degree of fermentation. With the standard roast (series 1), $T60$ is markedly inferior to the other types. With an increase in roasting time no significant differences could be detected.

It would therefore appear feasible to apply the incomplete block lay-out to the design of a laboratory assessment panel where a large number of samples have to be submitted to subjective tests.

We wish to acknowledge the help given by the Director of Cacao Research and other members of the staff of this Institute who constituted the assessment panels; and also the British Food Manufacturing Industries Research Association Cocoa Panel for supplying details of a method of preparation of liquors.

Table 3

	Series 1 Standard roast (55 min.)		Series 2 Length of roast		
	Under fermented	Fully fermented	50 min.	60 min.	70 min.
W.A.A.	5·56	5·22	5·20	5·27	5·13
$T.60$	4·11	3·00	4·33	5·27	4·80
$E1$	5·61	5·50	—	—	—
S.E. of a difference	±0·607		±0·445		
Significant difference ($P = 0\cdot05$)	±1·20		±0·880

Distribution of British Freshwater Amphipoda

Contributions by Hynes[1], Spooner[2] and Reid[3] have recently appeared in *Nature* on this subject. In referring to the spread of *Eucrangonyx gracilis* (S. I. Smith) Spooner states: "It is clear that the canal system has provided this species with an easy means of dispersal. It would be interesting, by a systematic examination of canals, to ascertain the northward limits of its range". It is therefore worthy of placing on record that I found *E. gracilis* in the Huddersfield–Ashton canal at Golcar near Huddersfield (Yorkshire) in July of the present year, this being apparently the most northerly record of this species in Britain to date. In one stretch of the canal it was the only amphipod found after considerable search and was present in some numbers. In an adjoining stretch it was found in company with *Gammarus pulex* (L.) and was considerably outnumbered by this species. Preliminary search of the canal at Marsden, some three miles to the south-west, revealed its presence there, so it is probably distributed throughout that section of the canal which lies to the east of the Pennines.

In an earlier series of communications, Cain and Cushing[4], and Reid[5] directed attention to the apparent increase in range of the semi-terrestrial amphipod *Orchestia bottae* (M. Edws.). Since that time I have established the existence of a more northerly station for this species, namely, at Huddersfield, and have placed this on record elsewhere[6]. Whether, as Reid suggests, these organisms have been present for some time but have remained undiscovered, or are indeed rapidly spreading northwards, is as yet undecided. Mr. D. M. Reid kindly checked the identity of both the above-mentioned amphipods.

FORTHCOMING EVENTS

Tuesday, September 11—Thursday, September 13

INSTITUTION OF MECHANICAL ENGINEERS and the AMERICAN SOCIETY OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1).—Conference on "Heat Transfer".

Tuesday, September 11—Thursday, September 20

BUILDING RESEARCH CONGRESS

(at the Institution of Civil Engineers, Great George Street, London, S.W.1).—Division 1: "The Influence of Mechanization and Prefabrication on Techniques and Cost of Building".

(at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2).—Division 2: "Building Materials".

(in Room 140, County Hall, Westminster Bridge, London, S.E.1).—Division 3, Part 1: "The Acoustics of Auditoria and Studios".

(at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1).—Division 3, Part 2: "The Heating and Ventilating of Buildings in relation to Summer and Winter Conditions".

(at the Royal Institution of Chartered Surveyors, 12 Great George Street, London, S.W.1).—Division 3, Part 3: "The Lighting of Buildings".

(at the Royal Institute of British Architects, 66 Portland Place, London, W.1).—Division 3, Part 4: Symposia on "The Problems of Three Specific Types of Buildings".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT (with an honours degree in science and/or agriculture, an interest in grassland husbandry and an aptitude for investigational and research work) TO THE ADVISORY OFFICER IN GRASSLAND HUSBANDRY, and ASSISTANTS (one honours graduate and one non-graduate) IN THE CHEMISTRY DEPARTMENT, for duties in connexion with soils and land fertility investigations—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (September 14).

ASSISTANT (Grade A) IN PHYSICAL CHEMISTRY, at Constantine Technical College—The Director of Education, Education Offices, Woodlands Road, Middlesbrough (September 15).

ASSISTANT CHEMIST (good experience in general analytical work essential, and knowledge and experience of sewage purification or bacteriology and bacteriological and enzyme chemistry an advantage)—The Chief Engineer, Middlesex County Council, Main Drainage Department, Mogden Works, Isleworth, Middx., quoting J.795.T (September 15).

CHEMIST (Assistant Experimental Officer grade) interested in agricultural research, to do routine sampling and analysis of grass and grassland products—The Secretary, Hannah Dairy Research Institute, Kirkhill, Ayr (September 15).

ELECTRON MICROSCOPIST for work on viruses at the Plant Virus Research Unit, Cambridge—The Secretary, Agricultural Research Council, 15 Regent Street, London, S.W.1 (September 15).

LECTURER IN AGRICULTURAL BOTANY—The Registrar, King's College, Newcastle-upon-Tyne (September 15).

LECTURER IN AGRICULTURAL SCIENCES, and a LECTURER IN AGRICULTURE (farm implements, building construction, etc.), at the Cheshire School of Agriculture, Reaseheath—The Director of Education, County Education Offices, City Road, Chester (September 15).

LECTURER IN INORGANIC CHEMISTRY in the Department of Chemistry, Colour Chemistry and Dyeing, and a TEACHER (with honours degree in mathematics) OF MATHEMATICS—The Principal, Technical College, Queen Street South, Huddersfield (September 15).

LECTURER IN THE DEPARTMENT OF NATURAL PHILOSOPHY—The Secretary, The University, Edinburgh (September 15).

SCIENTISTS (Grade II) (with good honours degree, or equivalent qualifications, in science or engineering, and some previous research experience) at London headquarters—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/366 (September 15)

PRINCIPAL SCIENTIFIC OFFICER IN THE DEPARTMENT OF SUPPLY, Long Range Weapons Establishment, Adelaide, for the organization and direction of research and development work in the fields of ballistic calculations and mathematical aspects of aerodynamics—The Senior Representative, Department of Supply, Canberra House, 87 Jermyn Street, London, S.W.1 (September 18).

ASSISTANT LECTURER (graduate in physics, chemistry or metallurgy) IN DENTAL MATERIALS—The Registrar, The University, Manchester 13 (September 20).

ASSISTANT (with honours degree in biochemistry, or its equivalent) IN BIOCHEMISTRY—The Secretary, The University, Aberdeen (September 21).

ENGINEER I at the Ministry of Supply in London, to be responsible for ordering and inspection of plant, planning and production of gauges and cutting tools for all types of ammunition manufacture—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.517/51A (September 24).

LECTURER IN MECHANICAL ENGINEERING, and an ASSISTANT FOR THE TEACHING OF CHEMISTRY and either Physics or Mathematics to a standard approximately that of the Ordinary Level of the General Certificate of Education—The Principal, Wigan and District Mining and Technical College, Wigan (September 25).

ELECTRICAL and MECHANICAL ENGINEERS (Experimental Officer grade) at a Ministry of Supply research and development establishment near London: (Ref. C.514/51A) MECHANICAL or ELECTRICAL ENGINEER with thorough experience in the design and use of small electromechanical devices; (Ref C.515/51A) MECHANICAL ENGINEER for tests and trials of small mechanical devices—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 29).

SENIOR SCIENTIFIC OFFICERS or SCIENTIFIC OFFICERS (ENGINEERS with a knowledge of assembling jig designs and able to appreciate the engineering principles of continuous production machinery) for micro-wave valve development and experimental production at an Admiralty establishment in Essex—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D 232/51A (September 29).

KEEPER OF THE DEPARTMENT OF BIOLOGY—The Director, Museum and Art Gallery, New Walk, Leicester, endorsed 'Keeper of Biology' (September 30).

MECHANICAL ENGINEER (with headquarters in London) to test and report upon various items of mechanical equipment—The Secretary, Forestry Commission, 25 Savile Row, London, W.1 (October 1).

PHYSICAL CHEMIST for investigations of high molecular weight substances by ultracentrifugation—The House Governor, Royal Cancer Hospital, Fulham Road, London, S.W.3 (October 1).

SENIOR EXPERIMENTAL OFFICERS (with H.S. Certificate with Mathematics or a science subject as a principal subject, or an equivalent qualification, and considerable technical experience of the raw material resources of the Colonial territories which are of plant or animal origin) in the Colonial Products Advisory Bureau (Plant and Animal)—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4067/51 (October 4).

CHAIR OF MINING—The Registrar, The University, Sheffield (October 6).

DIRECTOR OF THE AUCKLAND ART GALLERY, New Zealand—The Office of the High Commissioner for New Zealand, 415 Strand, London, W.C.2 (Auckland, October 31).

ELECTRICAL ENGINEER AND MANAGER to the Antigua Electricity Board—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M 28838.B.

GRADUATE SCIENTISTS to take part in research and for training in the scientific control of brewery operations in the Foundation's physical, chemical, analytical, biological or brewing laboratories—The Director, Brewing Industry Research Foundation, Nutfield, Surrey.

GRADUATES IN FUEL, CHEMISTRY, PHYSICS or CHEMICAL ENGINEERING, for laboratory and/or plant work: PRINCIPAL or SENIOR SCIENTIFIC OFFICERS (with good honours degree) as research section leaders, and SCIENTIFIC and EXPERIMENTAL OFFICERS for work in laboratory or on coke ovens and iron and steel plants—The Director, British Coke Research Association, 74 Grosvenor Street, London, W.1.

JUNIOR ASSISTANT PHYSICIST—The Secretary, South Manchester Hospital Management Committee, Christie Hospital and Holt Radium Institute, Manchester 20.

MATHEMATICIAN (M. or F., with honours degree, and knowledge of engineering, physics or chemistry an advantage)—The Secretary (Ref. A.28), British Coal Utilization Research Association, Randalls Road, Leatherhead, Surrey.

PHYSICAL or INORGANIC CHEMIST (preferably with one or two years research experience) to work on the surface structure of inorganic pigments, and a PHYSICAL CHEMIST (with a good knowledge of surface chemistry) for work on the physico-chemical relationships between pigments and organic media in surface coating materials—The Director, Paint Research Station, Waldegrave Road, Teddington, Middx.

PROFESSORS OF MATHEMATICS, PHYSICS, CHEMISTRY, ZOOLOGY, BOTANY, GEOGRAPHY, PSYCHOLOGY, PHILOSOPHY, ECONOMICS, ENGLISH, POLITICAL SCIENCE AND INTERNATIONAL RELATIONS, and HISTORY, at the University of Karachi, Pakistan—The Educational Attache to the High Commissioner for Pakistan, 39 Lowndes Square, London, S.W.1.

REGIONAL TRIALS OFFICER (with a university degree or diploma in agriculture and/or biology, and experience of conducting field trials)—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

SENIOR PLANT PATHOLOGIST (Senior Principal Scientific Officer grade) at the West African Cocoa Research Institute, Gold Coast—The Under-Secretary of State, Colonial Office, Research Department, Sanctuary Buildings, Great Smith Street, London, S.W.1.

SENIOR PHYSICIST, and an ASSISTANT PHYSICIST, to the Radiotherapy Department—The Group Secretary, Wolverhampton Hospital Management Committee, Royal Hospital, Wolverhampton.

SENIOR SCIENTIFIC OFFICERS and SCIENTIFIC OFFICERS at Admiralty experimental establishments in the vicinity of London, Baldock, Greenock, Haslemere, Portsmouth, Rosyth and Weymouth: PHYSICISTS (Ref. A.336/50A) capable of undertaking research or development in general physical problems, electronics, acoustics or thermodynamics, ELECTRICAL ENGINEERS (Ref. D.367/50A) qualified to undertake research, development or design in telecommunications, radar, electronics, instrumentation or light electrical mechanisms, MECHANICAL ENGINEERS (Ref. C.631/50A) capable of design, development or research work in light mechanisms, structures or hydrodynamics—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

STRUCTURAL ENGINEER (Public Works), Northern Rhodesia (Ref. 27322/222), and a SANITARY ENGINEER (Public Works), Northern Rhodesia (Ref. 27322/221)—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting the appropriate Ref. No.

TECHNICAL AUTHORS at a Ministry of Supply establishment at Chessington for the preparation of official instructional publications in the following groups: (Ref. D.376/51A) handbooks and circuit diagrams on the theoretical and practical (including servicing) aspects of airborne and ground electrical and electronic equipment, or on complete installations in aircraft, (Ref. D.378/51A) instructional publications on the theoretical and practical (including servicing) aspects of aircraft gun sights, bomb and torpedo sights, or complex types of aircraft navigation and computing instruments, (Ref. D.377/51A) instructional publications embracing aircraft and associated airborne and ground equipment, including airframes, electrical components and installation, air armaments, mechanical transport and airfield construction plant—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

MOVEMENTS OF BOOKS ACROSS NATIONAL BOUNDARIES

EARLY last year Sir Stanley Unwin reviewed, in a pamphlet entitled "How Governments Treat Books", some of the obstacles which taxation policy offers to-day to the free flow of books from one country to another. Sir Stanley quoted his examples from a summary of the regulations which affect the export of British books, prepared by the Publishers Association of Great Britain and covering some fifty-five countries. With the exception of those for the United States, which still discriminate against the British Commonwealth, most of these regulations apply to books from all countries. Besides taxes and customs duties, forms and formalities, as well as currency difficulties, also constitute serious obstructions to the dissemination of knowledge by the circulation of books.

Sir Stanley in this pamphlet, rightly emphasizing the value of books for the transmission not merely of knowledge but also of thought, pointed out that post-war governments are treating with scant respect this unique and priceless instrument for giving continuity and permanence to the free expression of thought. In many otherwise civilized countries, there is an increasing tendency to treat books as if they were merely an ordinary commodity of commerce, without cultural value or importance. The fundamental principle that the one thing no country can afford to hamper, limit or tax is knowledge no longer receives the respect that it enjoyed a century ago; and in the climate of opinion that is engendered by security measures, once they escape beyond the limits that the national interest requires in such matters as atomic energy, the progress of knowledge is bound to slow down.

Sir Stanley maintained in this pamphlet that the surest way of remedying the situation is ruthless publicity and exposure of all obstacles to the obstruction of the circulation of books. He instanced the campaign in Great Britain which in 1940 led promptly to the withdrawal of the Chancellor of the Exchequer's proposal to levy purchase tax on books as an example of the fact that no government finds it easy to defend the taxation or obstruction of knowledge when once it is publicly challenged, or likes to be held up to ridicule over its treatment of books as so many pieces of merchandise. Books, however, are not the only media for the exchange of knowledge, thought and culture, and the United Nations Educational, Scientific and Cultural Organization has done well to prepare and publish "Trade Barriers to Knowledge" (Paris: Unesco; London: H.M. Stationery Office, 1941. 6s.).

In this are set forth the tariff and trade regulations affecting the movement of educational, scientific and cultural materials from one country to another. This covers some forty-three countries and embraces regulations affecting not only books, periodicals, newspapers, etc., but also works of art, films, scientific instruments and apparatus, and materials specially for the blind. The book was compiled primarily as a practical handbook for publishing houses, film libraries, scientific laboratories and all organizations, as well as individuals, interested in obtaining such materials from abroad, or in sending them to other countries.

This publication is undoubtedly a useful step towards overcoming the formidable obstacle to the international circulation of such material which is presented by the complexity and variety of trade regulations in different countries and the inaccessibility of information concerning them. Confronted with this maze of restrictions, many organizations and individuals are discouraged from embarking on international exchanges of such materials, or even their sale in countries abroad. Even more important, however, is the service which the book should render to the efforts now being made in many countries for the reduction and progressive elimination of obstacles to the international circulation of educational, scientific and cultural material. The facts it records provide material for a sustained attack on many of the absurdities of the present situation; and an admirable introductory chapter, in which the development of those restrictions is reviewed and the attempts already made by Unesco to deal with the situation are explained, should assist in putting the facts in a true perspective.

It is indeed no pleasant picture that is presented by this manual, nor does the United Kingdom make a good showing. No consolation can be found in the reflexion that while modern technology has made possible the transmission of books, periodicals, newspapers, and other educational material across frontiers on an unprecedented scale, the present restrictions to such a flow have developed fortuitously rather than by design. Revenue derived from duties on such materials is relatively small, and rarely is any serious danger of competition with domestic industry involved. Frequently the regulation or restriction is trivial in the extreme, as derisory as it is irritating: it is the official outlook or attitude of mind revealed in the regulation that is so depressing.

The question of 'book tallies' in itself is trivial; but the official obtuseness which subjected them to purchase tax is an example of the lack of imagination which is responsible for many of the regulations, and which should be attacked unceasingly by all who are convinced that the restrictions placed upon the free flow of knowledge can and should be lifted. While such lack of imagination persists, there will be continual danger, for example, that legitimate barriers on the ground of military secrecy to the exchange of knowledge in certain fields of physics will be converted into barriers to the exchange of general knowledge. Muddled thinking rather than illiberal intentions are likewise responsible for allowing paper and books and paintings and other materials for conveying knowledge to become entangled in the general web of tariffs and currency regulations. While it is true that in Great Britain there is no purchase tax on books, even learned scientific and technical books are subject to a quota system, of 200 per cent of the value of pre war imports. Rising prices, not to mention the expansion of scientific and industrial research and the doubling of the university population in science and technology, make nonsense of any such figure.

What is required over the whole field is the play of a critical and imaginative intelligence bringing the regulations or restrictions into relation with realities, as is so often vividly illustrated in the minutes recorded in Mr. Winston Churchill's war memoirs, and sweeping away the waste of man-power on the issue or refusal of licences that serve no purpose. Full use should be made of the Unesco book to secure that action and to challenge the dubious restrictions here revealed. Unesco itself has already sought to reduce trade barriers to knowledge by sponsoring two international agreements which would raise the standard of dispensation. One, the Agreement for Facilitating the International Circulation of Visual and Auditory Materials of an Educational, Scientific and Cultural Character, had, by the beginning of 1951, been signed by eighteen countries, but only four (Canada, Norway, Pakistan and Yugoslavia) of ten ratifications required to bring this convention into force had been forthcoming. The Agreement on the Importation of Educational, Scientific and Cultural Materials, which would grant duty-free entry to publications, works of art, visual and auditory materials, scientific materials and articles for the blind, consigned to approved institutions, has been signed by seventeen countries, but also awaits the necessary ten ratifications to bring it into force. Besides in this way attempting to reduce the barriers to the international circulation of such material, Unesco is also endeavouring to help countries to meet their needs in this field, despite shortages of foreign currency, by encouraging exchanges of information on needs and resources, promoting trade agreements and stimulating domestic production. Here Unesco is working with the regional economic commissions of the United Nations, and some indication of its activities is given in the introductory section of the book. But its prime importance is the further weapon it affords educated opinion, in every country, for pressing even more insistently for the sweeping away of pedantic obstructions to the exchange of educational, cultural and scientific material of all kinds, and insisting that only those regulations are retained for which a reasoned case, acceptable to responsible and informed opinion, can be presented.

NATURAL AND SYNTHETIC DRUGS

Medicinal Chemistry

Chemistry, Biochemistry, Therapeutic and Pharmacological Action of Natural and Synthetic Drugs. By Prof. Alfred Burger. Vol. 1. Pp. xviii+577. (New York and London: Interscience Publishers, Inc., 1951.) 10 dollars.

TWO of the most outstanding characteristics of twentieth-century organic chemistry have been the amount of attention devoted to biologically active compounds, both natural and synthetic, and the striking successes which have attended investigations in these fields. It is not surprising, therefore, that many books have been written to survey and coordinate the results of these researches. There have been monographs on chemotherapy, antibiotics, vitamins, hormones, sulphonamide drugs, and similar topics, as well as on more restricted subjects within these fields, and also more general works covering, for example, the whole range of synthetic drugs. Prof. Burger's book is the first of two volumes in which he plans to give a comprehensive account of all classes of natural and synthetic drugs. The treatment is not confined to their chemistry, but includes also a description of their pharmacology, with some discussion of the mechanism of their action and of the relationships which have been found between chemical structure and biological activity. This is a commendable if ambitious project. Prof. Burger has himself made many important contributions in studies on synthetic drugs. But he could scarcely be expected to have first-hand knowledge of all the subjects on which he has written in the present volume. The book is inevitably somewhat of a compilation, and the treatment rather superficial. On the whole, though, it is a well-arranged compilation which is not unduly afflicted with the shortcomings often found in such works, and is a valuable and interesting work of reference. There is sufficient bibliography to direct the reader's attention to more authoritative and more extensive surveys of individual topics.

The compounds dealt with are classified according to their pharmacological effects, and the grouping together in a single chapter of all the drugs of various chemical types which exert a given pharmacological action is a very valuable feature. Volume 1 is largely concerned with pharmacodynamic drugs, whereas Volume 2 will deal mainly with chemotherapeutic agents which are used for combating diseases due to bacteria and other parasitical organisms. The volume under review includes accounts of general and local anæsthetics, hypnotics, anticonvulsant drugs, analgesics, cardiovascular drugs, autonomic drugs and antihistamine compounds. In addition, there are a few chapters on unrelated groups such as the vitamins and diagnostic agents. The book is attractively produced and the structural formulæ are printed in a particularly clear and pleasing manner. An unusual but useful feature is that the number of the chapter is given on all the even-numbered pages. The formulæ are numbered in a novel manner which might well be adopted by other authors. To each formula is attached the number of the chapter, in Roman numerals, followed by a figure in Arabic numerals representing the number within the chapter. This facilitates cross-reference, provides a unique label for each of the many formulæ throughout the book, and at the same time avoids the cumbersome and sometimes difficultly decipherable expressions resulting from the use of Roman numerals for a long series of formulæ.

Much confusion exists in naming drugs which are put on the market for clinical use. Half a dozen different names may be assigned by different manufacturers to the same product. Prof. Burger has attempted to rationalize his nomenclature. The now usual practice of treating trade names as proper nouns is followed, and widespread use is also made of the alternative names assigned by the Council of the American Medical Association. The trade names used are, very naturally, mainly American, and this may sometimes mislead British readers. For example, in the section devoted to the synthetic analgesic, Demerol, there is no reference to the British name of pethidine, or even to the name (Dolantin) given by the German discoverers of this drug. Incidentally, perusal of the chapter on analgesics shows the very wide range of structures associated with such action. In the preceding chapter attention is directed to the close structural resemblances between some hypnotics, anticonvulsants, analgesics, spasmolytics and antihistaminics. Those who have a prejudice against the use of drugs will perhaps be interested in the estimate that the American people consume about five to six million kilograms of caffeine per year in coffee alone.

The treatment of the chemistry of the drugs is very sketchy. Although structural formulæ appear in great profusion, only in very few cases has any attempt been made to show how they were established. Synthetic procedures are sometimes outlined; but this appears to be restricted to actual manufacturing processes. One wonders whether this is a good principle. In a book of this sort it seems scarcely necessary to devote a whole page to a series of formulæ illustrating the synthetic production of theophylline.

It is easy to find imperfections and occasional inaccuracies in a book covering such a wide range of subjects. The statement that "Paracelsus was a superficial quack" invites rejoinder. The first lecturer in chemistry in the University of Glasgow, William Cullen, was better known as a distinguished physician; but it is a little odd to find him described as "the Scotch surgeon". The early American work on anæsthetics is faithfully reported; but there is no mention of the introduction of chloroform by Simpson, of Edinburgh. The preparation of androsterone from cholesterol is wrongly attributed to Butenandt, the final elucidation of the structure of strychnine is attributed to Woodward, and there are similar historical distortions in regard to the structure of colchicine and of the cardiac glycosides. There is no warrant for, neither is there any meaning in, the statement that the carcinogenic properties of 9-hydroxymethylbenzpyrenes are more pronounced than those of corresponding methyl derivatives.

Taken as a whole, however, this book is an excellent piece of work and will be extensively used by those interested in synthetic drugs.

J. W. Cook

HISTORICAL APPROACH TO BACTERIAL CYTOLOGY

Elements of Bacterial Cytology

By Prof. Georges Knaysi. Second edition. Pp. xix+375. (Ithaca, N.Y.: Comstock Publishing Co., Inc., 1951.) 5 dollars.

THIS book has been considerably expanded since the first edition; but it is apparent that Prof. Knaysi's fundamental views upon the subject have been little affected by the greatly increased body of evidence which has accumulated in recent years since the resurgence of interest which he has done so much to promote. Only the briefest recognition is accorded to the acid-hydrolysis techniques by which the bacterial nucleus was, in fact, first convincingly demonstrated. He does not appear to have grasped the significance of the findings which have been made by this means, but apparently believes that the dumb-bell shape of the bacterial chromosome indicates transverse fission at the point of constriction.

The extraordinarily low standard of the photomicrographs by which the acid-Giemsa stain is illustrated, in contrast to the general excellence of the plates with which the book is lavishly provided, may explain his distaste for the method.

The work of the early bacterial cytologists is well reviewed, and many of their original drawings are reproduced. The value of this historical research should not be underestimated; but it would be even greater if it were combined with an equally full account of studies performed since the early nineteen-thirties. There is, for example, only a single, brief reference to the work of Robinow, and the entire chapters upon the cytology of Actinomycetes and Myxobacteria make none at all to the exceedingly important papers of Klieneberger-Nobel, only one of which is quoted in the whole book. Phenomena now widely accepted and repeatedly confirmed, such as the *L*-form mode of reproduction, multicellularity of the higher bacteria, variety of types of cell-division, and the autogamous processes associated with sporulation, are either treated with exaggerated reserve or totally ignored.

The format of the book is very attractive and the illustrations are particularly good. Electron microscopists will find much to interest them in the numerous micrographs which are included.

K. A. Bisset

THE HOME LIFE OF AN ASTRONOMER

Ninth Astronomer Royal

The Life of Frank Watson Dyson. By Margaret Wilson. (Published for the Dyson Family.) Pp. xvi+294+14 plates. (Cambridge: W. Heffer and Sons, Ltd., 1951.) 25*s*. net.

The biography of Sir Frank Dyson, ninth Astronomer Royal, by his daughter, Mrs. Wilson, gives a vivid account of the home background to his professional life. To those many who knew him personally and enjoyed his friendly hospitality in Greenwich or Edinburgh, this book will bring back happy memories of Dyson himself, his gracious wife and his cheerful family. But it must be admitted that the book would have gained considerably in value if it had included a full account of his scientific career and work written by an astronomical colleague. A clear picture of Dyson the man, as seen from the family circle, is given: Dyson the astronomer, however, is seen mainly from the same limited point of view, the account being supplemented by too little scientific appreciation. The result is a lack of balance in the picture.

This being said, we may turn with gratitude to what Mrs. Wilson has done in relating with such obvious enjoyment the story of the Dyson family. Like so many scientific men both in Great Britain and in the United States, Dyson was a son of the manse. His father was a prominent Baptist minister, and it was natural that Dyson as a young Cambridge graduate should follow his friend, T. R. Glover, as president of the Cambridge University Nonconformist Union. Typical of interests maintained throughout his life were the two papers he read to that body on "Robert Browning" and "The London Poor". But we must not omit, in speaking of his early days, to refer to the influence of his school. Dyson was fortunate in his headmaster and schoolfellows: Bradford Grammar School under Keeling produced a notable set of brilliant boys who made a mark for themselves later in life—it must suffice to mention here Benjamin Gott, William Rothenstein and John Coates. In Cambridge Dyson graduated as second Wrangler (the Senior Wrangler of his year, Sir Gilbert Walker, still happily survives); he was first Smith's Prizeman the year after Sampson, whom he also followed a year later as Isaac Newton Student. Years later, Sampson was to follow Dyson as Astronomer Royal for Scotland.

Dyson's father, possibly influenced by the friendship of Dawes, a well-known observer of double stars, had foretold at his birth that he would become Astronomer Royal. The opportunity came when Christie invited him in 1894 to succeed Turner as chief assistant at the Royal Observatory, Greenwich. Dyson accepted with alacrity, and from that day his career was marked out clearly for him. His observational work at Greenwich was varied with solar eclipse expeditions to Oran, Pulo Aoer Gadang and Sfax, at all of which he was favoured with fine weather: his luck in this respect never deserted him, and he was successful in observing six total eclipses of the sun in six attempts.

In 1905 came the move to Edinburgh, where Dyson's experience as Astronomer Royal for Scotland prepared the way for a return to Greenwich five years later as Astronomer Royal. Here he proved to be an administrator of sound judgment and keen practical sense, a greatly loved chief. One of his most striking decisions was taken during the dark days of the spring of 1918: that was to back the preparations for the Einstein eclipse of 1919. It is in the account of this eclipse that we find this book at fault on the scientific side—Einstein's special theory of relativity being ascribed to Newton.

One feature of Dyson's great influence on the astronomical world of his day was his participation in the international side of astronomy. Both as a ready and genial host to foreign astronomers visiting England and as one who co-operated fully with them in congresses, he formed an important link in the network of joint schemes which covers the astronomical world. It was only natural that in due course he should become president of the International Astronomical Union. This was one of many richly deserved honours that came his way. Perhaps none pleased him more than the honorary degree of Sc.D. conferred upon him by the University of Cambridge. With the final passage in the speech of his old friend, T. R. Glover, the Public Orator, we may fitly close this review—*Litteris, amicitiis, scientiis humanitate—sic itur ad astra.*

F. J. M. Stratton

TROPICAL ANIMAL NUTRITION

The Feeding of Farm Animals in India

By Dr. P. E. Lander. (Animal Husbandry Manuals.) Pp. xii+492+lii+46 plates. (Calcutta, Bombay, Madras and London: Macmillan and Co., Ltd., 1949.) 14 rupees; 25*s*. net.

The temperate zones of the world are well supplied with text-books which give information obtained from experiments published in many different and often inaccessible journals and reports. If progress is to be made in agriculturally backward areas in the tropics, similar books are essential, for the soils, crops and livestock are so different in the tropics that text-books written for temperate zones are of little real use and in some cases are often misleading.

This book, the first of its kind on animal nutrition in India, compiled from experimental results which have been obtained there and by one who has spent a life-time working on the subject, should be most useful to those who are doing advisory work on animal production not only in India but also throughout the tropics. The tables of chemical composition and digestibility, mineral and vitamin content of Indian feeding-stuffs will be invaluable for the rationing of animals in tropical countries, for until this book appeared they were to be found only in inaccessible publications and reports. These tables will do for the tropics what the tables of Kellner, Armsby and others have done for temperate climates. In general, the book follows the traditional lines of those on animal nutrition, but with special reference to Indian conditions, and includes sections on the feeding of buffaloes and camels. A chapter on some harmful foods and famine fodders supplies useful information rarely found in nutrition books written for temperate climates.

Perhaps the most important respect in which the book differs from those written for temperate areas is that it starts with the soil and deals with its deterioration and erosion from overgrazing, an aspect of animal nutrition which is of special importance in the tropics. As the author states, the ultimate solution of the problem of feeding animals in India lies in the restoration of the proper equilibrium between the soil and the human and cattle population.

JOHN HAMMOND

BIRDS OF A LOW RAINFALL REGION

A Handbook of the Birds of Western Australia (with the exception of the Kimberley Division)
By D. L. Serventy and H. M. Whittell. Second edition. Pp. viii+384. (Perth: Paterson Brokensha Pty., Ltd., 1951.) n.p.

AUSTRALIA, scarcely less than Great Britain, has of recent years been flooded with 'Nature books' of dubious accuracy and of poor quality. These have been hastily put together in order to exploit the growing desire of the public for information about animals, particularly birds.

The present volume is a refreshing departure from the general run of ornithological literature. It is the result of much painstaking scholarship, and it contains information that will interest any biologist who is concerned with the effects of landscape aridity on form, of environmental change on distribution, or the influence of irregular and scanty rainfall on the breeding seasons of animals. It is, then, far more than a mere handbook of the fauna of a single restricted area within political boundaries.

Certain parts of the book are of especial interest in that they throw further doubt on the validity of the day-length hypothesis in the regulation of avian breeding seasons. This notion has gained almost universal acceptance since Rowan's epochal demonstration, about twenty-five years ago, that the reproductive mechanism of vertebrates can be stimulated by increased lighting. There can, of course, be no question that the hypophysis can be indirectly influenced and gonad modification induced in many species by artificial photostimulation; but the importance of day-length as an ultimate, or even as an initiating factor, in the timing of avian breeding seasons under natural conditions has been seriously questioned by recent work in Britain on British and Australian species. Serventy and Whittell point out in the volume under review that in Western Australia light increases in duration from June until December; but, in the southern parts of the country, many species ovulate from mid-April onwards. In the north-west, breeding occurs mostly in the winter, while in the south-west most birds ovulate during the spring months when light is increasing. In each region there is a very pretty correlation between sexual activity and rainfall, and as a consequence, the young are launched from region to region at times most propitious for their survival. In one area where spring ovulation is normal, a heavy and unseasonal deluge was followed by widespread autumn reproduction. A hundred miles away where the rains did not penetrate, breeding did not occur until the following spring. This kind of information supports the concept that after the post-nuptial period of gonad metamorphosis (which varies in duration from species to species) many birds are ready to undergo reproductive activity immediately there occurs in the environment the combination of external stimuli to which they are hereditarily attuned to respond. Breeding can occur quite irrespective of changes in day-length. Serventy and Whittell have further information that suggests the operation of an internal rhythm among sea-birds. The silver gull (*Larus novæ-hollandiæ*), for example, has a winter and a spring breeding population on the same small coastal island.

The present "Handbook" contains a great amount of detail that is chiefly important to local naturalists, including a most excellent history of Western Australian ornithology dating from the seventeenth century explorers such as van Hillegom, de Vlamingh (who discovered that a black swan was not a *rara avis* after all) and the remarkable English buccaneer, William Dampier. It is to be hoped that subsequent editions may include the birds of the remote Kimberley region with its 'incubator bird' (*Megapodius*), fruit-pigeons, pittas and other forms of tropical origin and affinity. In fact, one cannot think of two men better qualified to write a much-needed modern handbook covering the birds of the entire continent of Australia.

A. J. MARSHALL

SIX-FIGURE MATHEMATICAL TABLES

Chambers's Shorter Six-Figure Mathematical Tables
By Dr. L. J. Comrie. Pp. xxvi+388. (Edinburgh and London: W. and R. Chambers, Ltd., 1950.) 12s. 6d. net.

WHEN accuracy in simple numerical calculations greater than that attainable by the use of the common four- or five-figure tables has been desired, it has been usual to resort to Chambers's seven-figure tables, although they are restricted to common logarithms and the trigonometrical functions. The question of a revised edition of the latter tables was referred to Dr. L. J. Comrie, and the substance of his recommendations was that a wider range of elementary functions should be included and that they should be on a six- and not a seven-figure basis. The main reason for the latter recommendation was that it made linear interpolation possible within a reasonable compass, and it was defended on the grounds that, apart from certain specialist needs already adequately catered for, ordinary scientific and technological calculations would need higher accuracy only very rarely indeed. The result was "Chambers's Six-Figure Mathematical Tables", in two volumes. The volume now under review is essentially an abridged version of these, containing a selection of the more useful tables. Many users will find this collection adequate for their needs, and there is obvious convenience in a single volume, if its contents do indeed suffice.

Most of the pages have been taken direct from the two-volume edition, but some have been reset at a wider interval. As will be seen from a summary of the contents which is given below, the range of elementary functions is quite well covered, which was certainly not the case with the old 'Chambers'. Much more emphasis has been laid on natural than on logarithmic values, since the former are much more frequently required in these days of mechanical computation.

The main tables give common logarithms, logarithmic and natural trigonometric functions (with argument in degrees, minutes, and seconds), circular functions (argument in radians), exponential and hyperbolic functions, natural logarithms, inverse circular and hyperbolic functions, powers, roots, reciprocals, factors and factorials. Pages of formulæ relating to the functions tabulated, lists of series and integrals, formulæ and tables of coefficients for interpolation and for numerical differentiation and integration, and sundry conversion tables, are included, along with copious worked examples showing how the tables may be used most efficiently.

The tables are planned so that, in general, linear interpolation gives the greatest accuracy attainable from them, and in the main tables the appropriate proportional parts are provided at every opening. In the few ranges where the second difference correction cannot be neglected, the user's attention is directed to this fact by the printing of the first differences in italics. Bessel's formula for applying the necessary corrections is advocated, and tables of the values of the coefficients are given. Other cases where linear interpolation becomes difficult are met by auxiliary functions (for example, $s(x) = \log x - \log \sin x$ for small x). For slowly varying functions (and this includes most of the auxiliary functions just mentioned), so-called 'critical' tables are provided.

Apart from the refinements of typography and lay-out which one associates with the name of Dr. Comrie, one cannot fail to be impressed by the evidence of the thought given and the care taken to provide the user with the maximum of information in the minimum of space, and the maximum accuracy with the minimum labour. Almost every page contains some ingenious device—many invented by Dr. Comrie himself—directed to one or other of these ends. The book is well produced, and is bound so that it lies flat at any opening, a great convenience in use. It represents remarkable value for money.

This was the last of Dr. Comrie's projects which he was able to see completed. By it alone one can measure both his greatness as a maker of tables and the loss we have sustained by his passing.

W. G. Bickley

HUMANITY AND THE HELM

The Human Use of Human Beings

Cybernetics and Society. By Prof. Norbert Wiener. Pp. xi+241. (London: Eyre and Spottiswoode (Publishers), Ltd., 1950.) 18s. net.

SOME two years ago, Prof. Norbert Wiener published a book on cybernetics, in which he developed the subject mathematically, mainly with the object of clarifying certain researches in communication-engineering, to which he has made notable contributions.

He now follows this up with a volume more specifically aimed at the layman, and naturally hopes that it will keep its bearing fair and square upon the target (however erratic that target's course may be), as all good cybernetical devices should.

The sub-title "Cybernetics and Society" is appropriate, although we are told much more about the latter than about the former. Steering committees have become accepted in twentieth-century affairs: cybernetics and the whole armoury of calculating machines are means (theoretical and existential) of performing many functions for mankind from without rather than from within. The perils of all this are manifest, and need little emphasis.

Once the outlook is grasped, the course of this book follows almost automatically: entropy, language, semantics, communications, industrial revolutions (two), and the voices of rigidity. That Prof. Wiener has a profound respect for the human being is of the essence of these pages, and on that score alone his work commands both respect and gratitude. What, however, is less obvious—and sometimes a little irritating—is whether or not he is referring specifically to his own country (the United States) or whether his edicts are meant to apply universally. There are several instances wherein one discovers only at the end of a long disquisition that its purpose all along has been strictly limited, whereas whole paragraphs read like sweeping generalizations.

Some of the more physical concepts are especially valuable. One is our natural tendency to concentrate upon the 'islands' of decreasing entropy ("Let us eat and drink, for to-morrow we die", in fact), rather than upon the 'oceans' for which $S = k \log W$. Here 'Baltzmann' for Boltzmann (repeated in the index) is a deplorable slip, although the status of the *Wärmetod* needs some thought at the moment. This is on account of 'open systems' of thermodynamics recently investigated by Bertalanffy and others; they may turn out to be the thermodynamics of the biological world, and hence of major consequence for society and for cybernetics.

Prof. Wiener is forthright about educational matters. We all come under his lash; but the heaviest strokes are reserved for his own country. The present reviewer, however, would like to record his delight—in visiting Prof. Wiener's own institution on two separate occasions—in finding so much provision for the study of the humanities (in the midst of technics), and for the liberal arts; and again, there is the University of Buffalo, straining both its finances and its academic man-power in a noble effort to give individual teaching its highest expression. This, too, encourages the hope that all is not lost.

For the rest, Prof. Wiener's apocalyptic utterances will doubtless bide their time, for they speak of things perhaps unknowable as yet.

F. I. G. Rawlins

BRITAIN'S SCIENTIFIC SHRINES (6)

By ENG.-CAPTAIN EDGAR C. SMITH, O.B.E., R.N.

THE NORTH-WESTERN COUNTIES

AMONG the men of science who passed their lives in the north of England, a special place belongs to the young clergyman Jeremiah Horrocks (1619 ?–41) and his friend William Crabtree (1610–42 ?), the first of mankind to observe the passage of the planet Venus across the sun's disk. Both were Lancashire men, Horrocks being a native of Toxteth, now within the boundaries of Liverpool, and Crabtree a native of Broughton, near Manchester. The story of their achievement is fully told in Grant's "History of Physical Astronomy". From 1632 until 1635 Horrocks was at Emmanuel College, Cambridge. Home again, he became a tutor, then went as curate to Hoole, eight miles south-west of Preston. Crabtree, on the other hand, was a clothier, but by the age of twenty-six was in correspondence with Horrocks. Their calculations led to the prediction that the transit would occur on Sunday, November 24, 1639, and both prepared to observe it, one at Hoole, the other at Broughton. Favoured by breaks in the clouds at the critical time, both were successful and, as Grant wrote: "Thus did two young men, cultivating astronomy together in a state of almost complete seclusion in one of the northern counties of England, enjoy the privilege of witnessing a phenomenon which human eyes had never before beheld, and which no one was destined again to see until more than a hundred years had passed away". What Horrocks might have achieved had he lived longer no one can say, but his early death, on January 3, 1641, must be regarded as one of the great losses to science in Britain. Crabtree also passed away within a year or two, and owing to the upheaval of the Civil War, the papers and correspondence of both barely escaped destruction. Though in a letter sent to King George III in February 1768, asking for assistance in observing the transit of 1769, the Royal Society referred to Horrocks, neither then, nor for long afterwards, was anything done to honour Horrocks's memory, and it remained for the Lancashire gardener, weaver and scientific lecturer, Moses Holden (1777–1864), to erect at his own expense in 1826 a memorial to Horrocks in St. Michael's Church, Toxteth. Later on, in 1859, a memorial chapel and window were added to Hoole Church, and in 1879, when the transits of 1874 and 1882 were attracting much attention, a tablet with an inscription by Dean Stanley was placed at the west end of Westminster Abbey. Four years later, one of the frescoes by Ford Madox Brown in Manchester Town Hall was devoted to Crabtree and his observation of the transit.

Other frescoes in the Manchester Town Hall recall the work of the canal builders, Brindley and the Duke of Bridgewater, John Kay of Bury, the inventor of the 'fly shuttle', and Manchester's most famous man of science, the Quaker teacher, chemist and physicist, John Dalton. There was never any likelihood of Dalton's work being forgotten, for after his death on July 27, 1844, wrote Lord Playfair, "Manchester gave him the honours of a king. His body lay in state and his funeral was like that of a monarch". His massive granite tomb is in Ardwick Cemetery and his statue, together with that of his pupil and successor, James Prescott Joule, stands in the entrance to the Town Hall. Dalton hailed from Cumberland, being born on September 6, 1766, at Eaglesfield, near Cockermouth, and near by in the graveyard of Pardshaw Hall is a memorial to him erected a few years ago by the Society of Friends. Nearly a century before Dalton was born, Cumberland was the birthplace of another famous Quaker scientific worker, George Graham (1673–1751), who was born at Horsgills, in the parish of Kirklinton; but he went to London to serve an apprenticeship, and now lies with his master, Thomas Tompion, in Westminster Abbey, whither he was carried on the night of November 24, 1751, his pall being supported "by Dr. Knight, Mr. Watson, Mr. Canton, Mr. Short, fellows of the R.S., Mr. Catlyn, and Mr. Bird, intimate friends of his". In the eighteenth century, when the majority of British natural philosophers devoted themselves to physical inquiries and astronomy, London was a great centre for clock, instrument and telescope makers, among whom none had a higher reputation than Graham and his follows from the North Country, among whom were John Harrison (1693–1776), of Yorkshire; John Bird (1709–76), a native of Durham; Jesse Ramsden (1735–1800), another Yorkshireman; Thomas Earnshaw (1749–1829), who was born at Ashton-under-Lyne, Lancashire; and Edward Troughton (1753–1835), like Graham a native of Cumberland. The clocks, chronometers, sextants and telescopes of these great artists were found in ships and observatories all over the world. A bust of Troughton is in the keeping of the Royal Observatory, Greenwich, the tomb of John Harrison in Hampstead churchyard was reconstructed in 1879 by the Worshipful Company of Clockmakers, and in 1931 the Company joined with the British Horological Institute in erecting a tablet to Earnshaw outside the church of St. Giles-in-the-Fields, Bloomsbury, where Earnshaw worshipped and was buried. Of the other men of science of whom Cumberland can boast, Dr. William Browning (1711–1800) practised for many years at Whitehaven, where he made experiments on the gases from mines. In 1766 he was awarded the Copley Medal of the Royal Society for his "Experimental Enquiry into the Mineral Elastic Spirit or Air contained in Spa Water", and a few years later assisted Franklin with his experiments on stilling the waves of Derwentwater by the use of oil. Browning died in retirement at Ormathwaite, near Keswick. From Whitbeck in Cumberland came another original and versatile man of science, the Rev. William Pearson (1767–1847), a promoter of the Royal Institution, a founder of the Astronomical Society, and the owner of an observatory at South Kilworth, Leicestershire, of which he was rector for thirty years and in the church of which he has a memorial.

There are other names which might perhaps be included in this brief review of the worthies of Cumberland; but no excuse is needed for recalling that it was at Stoneraise Place, Wigton, on July 2, 1862, that Sir William Bragg was born. From 1923 he was Fullerian professor at the Royal Institution and director of the Davy Faraday Research Laboratory and during 1935–40 president of the Royal Society. He died on March 12, 1942.

Westmorland no less than Cumberland had her mathematicians and experimentalists, among whom were William Gibson (1720–91), a native of Boulton, near Appleby; Adam Walker (1731 ?–1821), who was born at Patterdale; and the blind John Gough (1757–1825), of Kendal. All having taught themselves taught others. Gibson, who had a school at Cartmel in Lancashire, was a correspondent with many other mathematicians; Adam Walker became a successful lecturer on scientific subjects in London and at Westminster, Eton, Winchester and other schools; and Gough, at his school at Kendal, counted among his pupils Dalton and Whewell. Though blind from the age of three, Gough made many contributions to the *Transactions of the Manchester Literary and Philosophical Society* and other periodicals. Among Walker's friends was the painter George Romney, who died in Kendal in 1802, and in the National Portrait Gallery is Romney's picture of Walker, his wife and daughter and three sons, the youngest of whom, Deane Franklin Walker (1778–1865), continued his father's lectures at the great public schools. The contemporaries of Gibson, Walker and Gough included the Rev. Anthony Shepherd (1721–96), a native of Kendal, who became Plumian professor at Cambridge, master of mechanics to George III and canon of Windsor; Bishop Richard Watson (1737–1816), who was born at Heversham and is buried and commemorated in Windermere Church; and Thomas Garnett (1766–1802), of Casterton, who was trained as a surgeon by John Dawson (1734–1820), of Sedburgh, and at Edinburgh, and became the first professor of natural philosophy in the Andersonian Institution, Glasgow, and also the first professor of natural philosophy in the Royal Institution. His early death was due to typhus fever. Watson, like Shepherd, was educated at Cambridge, and though, as he himself admitted, he knew nothing of chemistry, was appointed professor of that subject. The post, however, was admirably filled, and Watson afterwards published volumes of chemical essays. To him the Navy owed its first lightning conductor, a chain of copper rods, one end of which, on the approach of a thunderstorm, was triced to the masthead while the other end was allowed to trail in the sea. Like others, Watson was a pluralist—he held several livings and during 1782–87 was Bishop of Llandaff. He died at his estate, Calgarth Park, Westmorland.

The mention of that rather remarkable character, John Dawson, justifies a short detour from Westmorland to Sedburgh and Dent in the north-west of Yorkshire, for Dawson, overcoming his early lack of schooling, not only became a competent surgeon but also a good mathematician, who saw several of his private pupils become senior wranglers. Among this group was Adam Sedgwick (1785–1873), the great geologist, son of the curate of Dent, in the beautiful Dentdale, which was described in a letter by Airy in 1841 and again by A. C. Ramsay in a letter in 1865, who from "Dent, Kendal" wrote: "to old Adam Sedgwick telling him how pleased I am to be in his old home . . .". Sedgwick was perhaps the most popular man in Cambridge, and Geikie wrote of his "hard featured yet noble face, eyes like an eagle's, manly alike in body and mind, full of enthusiasm, ready and graphic in talk, generous and sympathetic, shrinking from no toil either at home or abroad in furtherance of his chosen branch of science". He was buried in Trinity College Chapel, and his name is perpetuated by the Sedgwick Museum of Geology, in which is his statue.

Entering Lancashire from Westmorland, just across the border are found Whittington, the birthplace of the shoemaker, gunner, experimenter and lecturer, William Sturgeon (1783–1850), who gave the world its first electromagnet, and Lindale, where can be seen the cast-iron column erected to the famous iron-master John Wilkinson, who lies in a cast-iron coffin not far away. Another column, but of stone and fashioned like a lighthouse, can be seen on Hoad Hill, Ulverston. This was erected in 1850 in memory of Sir John Barrow (1764–1848), who, long the secretary of the Admiralty, promoted Arctic exploration and was the virtual founder in 1830 of the Royal Geographical Society. Barrow's birthplace was a small cottage at Dragley Beck, Ulverston, and in this is a tablet recalling his services and referring to the remarkable vigour of his mind. The cottage was presented to Barrow's son, who gave it to the Ulverston Urban District Council together with the plans of the monument on Hoad Hill. Another spot near Ulverston, Lowick, was the birthplace of Dr. Joshua King (1778–1857), another of Gough's pupils. He became a fellow of Queens' College, Cambridge, and died in the President's Lodge; he was the predecessor of Sir George Stokes in the Lucasian chair of mathematics. Sturgeon's career began with his apprenticeship to a harsh and mean shoemaker, but it took him into the Westmorland Militia, into the Royal Artillery at Woolwich, to the East India Company's College at Addiscombe, to the Adelaide Gallery of Practical Science in London, and in 1840 to the Royal Victoria Gallery at Manchester. Known to Dalton and Joule and a contributor to the *Transactions of the Manchester Literary and Philosophical Society*, he died as poor as when he was born, and was buried at Prestwich, near Manchester. In 1847, it is recorded, he gave four lectures on electricity and optics at the Green Dragon Inn, Kirkby Lonsdale, Westmorland, two miles from his birthplace, and in Kirkby Lonsdale Church is a marble tablet to his memory.

If a century ago Sedgwick was the most popular man in Cambridge, William Whewell (1794–1866), who was born at Lancaster, was certainly the most masterful. His energy, learning and influence were immense, and he ruled Trinity College like a captain does a battleship. The son of a carpenter, he attended Lancaster Grammar School, and before entering the University of Cambridge read mathematics with John Gough. From his eighteenth year Cambridge was his home. Sir Francis Galton, who belonged to a younger generation, and who graduated from Trinity College in 1844, in his "Memories of my Life", gave an amusing account of the great man courting Lady Affleck, and quoted the lines:

> "You may roam where you will through the
> realms of infinity
> And find nothing so great as the Master of
> Trinity"

which he had from Lord Kelvin; he also said that readers of Whewell's "Life" would gather from it "little idea of the rough power of the man and his too frequent overbearing attitude. In after days," Galton added, "he invited me to the Lodge, where I found him unexpectedly gracious." To-day, a statue of Whewell stands in the ante-chapel of Trinity College beside those of Bacon, Barrow, Newton, Macaulay and Tennyson, and in Lancaster Church he has a memorial window. Lancaster was also the birthplace of Whewell's famous friend and contemporary, Sir Richard Owen (1804–92), whose destiny took him first to Edinburgh and then to London. Yet another son of Lancaster was Henry Cort (1740–1800), the Navy Agent who revolutionized the wrought-iron industry and gave the new race of engineers and shipbuilders the bars and plates needed for their rails, boilers, engines, bridges and ships. Misfortune dogged his later years, and like many another benefactor who has died poor, he passed away unhonoured and unsung. His grave in Hampstead churchyard long lay neglected, until in 1905 an American citizen, Charles H. Morgan (1831–1911), of Worcester, Mass., a past president of the American Institute of Mining Engineers, found and renovated the tombstone and provided a bronze tablet for the porch of the church at Hampstead and another for the church at Lancaster.

From Lancaster to Preston is a matter of eighteen miles, and at Preston begins the great manufacturing area associated with the eighteenth century pioneers of the textile industry. Preston itself was the birthplace of Richard Arkwright; Blackburn and Accrington were the scene of the early labours of James Hargreaves (1720 ?–78). Bury was the home of John Kay (1704–?), and Bolton the birthplace of Samuel Crompton (1753–1827). Hargreaves appears to have no memorial; but Kay's cottage is still standing and the Bury and District Textile Society is trying to have it preserved. Bolton has long done justice to the memory of Crompton, for his statue stands in one of its squares and his old home, "Hall-i'-th'-Wood", a small timbered mansion, has been preserved through the action of another famous son of Bolton, the first Lord Leverhulme (1851–1925). Horrocks's connexion with Hoole, near Preston, has already been mentioned, and Preston now, in Moor Park, has its own Jeremiah Horrocks Observatory. To the north of the town at Woodplumpton is to be seen the memorial to the clergyman's son, Lieutenant Henry Foster (1796–1831), R.N., who accidentally lost his life in the Chargres River. He had entered the Navy at the age of sixteen as a volunteer, and his scientific work during Arctic voyages had gained for him in 1824 the fellowship of the Royal Society and in 1827 the Copley Medal. In 1828, given the command of the *Chanticleer*, he set out on a long voyage of scientific research from which he never returned.

"At the time of Crompton's birth," said *The Times* on the occasion of his centenary in 1927, "Lancashire was a wild stretch of country and the towns in it contemptible; at the time of his death it was a hive of prosperity." This prosperity was shown by the great increase in population. It is believed that in 1700 the five most populous counties of England were Middlesex, Somerset, Gloucestershire, Wiltshire and Northamptonshire; in 1800 they were Middlesex, Lancashire, the West Riding of Yorkshire, Staffordshire and Warwickshire. With this increase of population had come the construction of canals, the improvement of roads and the speeding-up of traffic. No place felt the impact of the Industrial Revolution more than Manchester, the population of which increased from 22,000 in 1780 to 160,000 in 1824.

It was the beginning of this period which saw, in 1781, the foundation of the Manchester Literary and Philosophical Society, which became almost a Royal Society for the north-west. Since the days of Crabtree, until the middle of the eighteenth century, Manchester had produced few if any notable men of science; but with the founding of the Literary and Philosophical Society it became a centre for the scientifically minded, and the story of the Society and of the College founded by the will of John Owens (1790–1846), and of the University to which the College gave birth, would fill many a volume. But all that can be done here is to recall the beginnings of things and some of the men who brought them to pass. As in so many matters, it was the medical men who set the ball rolling, and the two names most closely associated with the founding of the Society are those of Dr. Thomas Percival (1740–1804) and the surgeon-apothecary Thomas Henry (1734–1816). It was at the house of Percival that the Society was brought into being; it was Percival who was its first president and it was Henry who was its first secretary. Born at Warrington, and a student of the Warrington Academy, where Priestley at one time taught, Percival took his degree of M.D. at Leyden in 1765 and two years later set up in practice in Manchester, becoming known as one of her most public-spirited citizens. He died in Manchester but was buried in Warrington Church. Henry was no less active in the interests of science and the people of Manchester, and when he died he left a son, Dr. William Henry (1774–1836), who, like his contemporary Dalton, added greatly to the fame of the Philosophical Society and gained for himself the coveted Copley Medal. Refined in manner, eloquent in speech, his society was much coveted. "He was an accomplished and original man; one who advanced science and took a prominent place among the chemists of the age." It was in 1794 that Dalton became a member of the Society, and for more than forty years it was his scientific home. Within its walls he taught, lectured, wrote and experimented and was its president from the time of the death of Thomas Henry, being elected each year unanimously save for a single vote—his own! Joule, who was born at Salford in 1818 and died at Sale, Cheshire, in 1889, of course, belonged to a later generation, but it was on him Dalton's mantle fell.

From 1799 onwards, the home of the Society was at 36 George Street, and when the Society in 1931 celebrated its one hundred and fiftieth birthday, it was addressed by Sir J. J. Thomson (1856–1940), who was born at Cheetham, Manchester. At that time it was said that No. 36 George Street "has externally an old world appearance, with pillars in front and a porch finely panelled in mahogany. Internally it is most attractive and preserves an atmosphere of studious calm in a district long ago given up to commercial activities. . . . Of Dalton relics the Society has an unequalled collection." On the night of December 24, 1940, during an air-raid, the building, its memorial tablet to Percival, its busts and portraits of distinguished men, and its library of 50,000 volumes, were completely destroyed, and from the debris all that was recovered relating to Dalton was his watch, a eudiometer and some charred papers. The same fate also overtook the Cross Street Unitarian Chapel, where both the Henrys were buried.

The temptation is to continue the story of the scientific worthies of south Lancashire, and to review the work of the founders of her great chemical industry, to visit the haunts of some of her famous engineers, to trace the birth and development of the scientific institutions of Liverpool and to say something of the interesting Liverpool Observatory and Tidal Institute, which, like the Royal Greenwich Observatory, was founded in the interests of navigation.

But perhaps sufficient has been said of the work of the pioneers in a county which, in more recent times, has seen some of the most notable triumphs of the methods of scientific research of which Dalton and Joule were such masters.

WORLD COMMUNICATIONS: THE IMPACT OF SPEED

THE Division for Social and International Relations of Science of the British Association held an open meeting on "World Communications: The Impact of Speed" in the Pollock Hall, University of Edinburgh, on August 13; Sir Harold Hartley was in the chair.

Sir Edward Appleton, principal and vice chancellor of the University of Edinburgh, opened the discussion by sketching briefly the technical advances of radio which permit intelligence to girdle the earth almost instantaneously. He emphasized that these changes have all occurred within approximately the past half-century. Marconi's morse signals were the first relatively simple step; but even they were capable of trans-Atlantic transmission by the then unexplained natural bonus provided by the Heaviside layer, which reflects radio waves back to earth and continues to zig-zag them around its circumference. It required, however, the development of the radio valve to make the more complicated speech and music signals amenable to transmission.

The importance of research into the reflecting properties of the ionosphere in the technical advance of international radio communications was emphasized by Sir Edward, and he explained how its variation demands the use of compromise wave-lengths the value of which changes over the twenty-four hours. Ionospheric 'radio weather' is subject, however, only to slow and small change, which, after twenty years research, is predictable.

The competition for the short wave bands which girdle the earth is tremendous, because of their unique value to instantaneous world-wide transmission, and this impact of speed encourages disregard of international agreement of wave-bands, especially for purposes of propaganda.

For broadcasting within fairly narrow national boundaries, the medium wave-lengths are favoured. But here the increase of night-range caused by reflexion creates the international interference nuisance, and for this reason very short, non-interfering, escaping wave-lengths are being favoured for broadcasting speech and vision domestically. They would also relieve the congestion on the longer wave bands. The impact of speed is the demand for more people to use more of it.

Concern is being felt about the amount of radio noise and the need to reduce the unnecessary element in it. The prime need for simple code message, speech or television is to convey it untrammelled. There is enough radio noise inherent in broadcasting. In addition, the wastage of radio channel space on propaganda was deplored by Sir Edward, for large areas must be flooded with strong signals to reach inferior receivers. If the speed of radio communications could be accompanied by world peace and co-operation, greater radio efficiency would result. Verbiage in the air could be cut down to advantage, more especially in English. These points emphasized the urge to economy in radio channel space which these much-sought speedy communications demand.

Sir Edward concluded that the disadvantages faced by radio to-day are largely of man's own making. Science is neutral and will continue to seek truth, and, if the impact of speed is to be for good, it is for ourselves to make it so.

Sir Ben Lockspeiser, secretary of the Department of Scientific and Industrial Research, followed, tracing the impact of speed in aviation. The 10 miles per hour flight of the Wright Brothers heralded a transport revolution because of hitherto unsurmountable barriers being lowered. But the Wright aircraft was all excrescences, and, as these were shorn away in later types, ever-improving speeds were achieved. Cockpits were built in, struts and bracing wires disappeared, monoplane replaced biplane, undercarriages were retracted, and all manner of gear was built flush in the structure to give the streamlined modern aircraft. But with the streamlining of the aerodynamicist had to come the research of the structural engineer and engine designer to reduce weight as well as drag. With increasing speed comes increasing drag; but an economic margin of pay load and range must be maintained for military or commercial purposes, and the impact of speed is to induce the collaboration of all scientific workers to reduce structural weight, engine weight per horse power and fuel consumption. Metallurgist, structural engineer and aero engine makers have combined to reduce weight, and fuel consumption was reduced until the arrival of 100 octane fuel.

Profile drag has been cut to a minimum by wind-tunnel experiment and the mathematical analysis of results by aerodynamicists.

Despite all these gains in speed, a halt to increase would have come in 1945, but for Whittle's jet engine, with its high thrust and propulsive efficiency increasing with speed, enabling the shock waves near the sonic barrier to be overcome. The propeller-driven aircraft was unlikely to have exceeded 550 miles per hour.

New aerodynamic design with swept-back wing, delaying onset of shock waves, combined with the use of thin wings, slim fuselage, swept-back tail and fin surfaces and jet engines have created the new efficiency embodied in the British Comet transport aircraft, the impact of the speed of which will bring London within 18 hours of Johannesburg.

The historical review of world communications over the past half-century having been traced by the first two speakers, Dr. Edward Warner, director of the International Civil Aviation Organization, considered the impact of speed on contemporary world society, and especially the impact of the aeroplane's speed. Here he gave a warning that increased speed is not the only significant characteristic of air transport. Of all the revolutionary changes in world transport, aircraft spell the greatest flexibility and emancipation from routes and permanent way.

Air transport has created quite new social, economic and political conditions. The 'remote places of the earth' have become economically accessible and new culture contacts have sprung up, with inevitable awakening of interest in world affairs for remote peoples. The aeroplane has brought medical services where there were none before. Commercial relations, economically prohibited hitherto, have flourished, and the aeroplane has become the *raison d'être* for many new communities and for the revitalization or altered status of older ones. This is true even in such densely populated areas as the United Kingdom, as witness the Scottish Islands. This is the more spectacular impact of speed and flexibility in air transport.

Of more consequence is sheer speed between established centres of population and commerce. Transport of persons between such areas may be for personal or business reasons, each with its peculiar consequences. Air transport has eliminated the time-factor as a deterrent to travel or shipment, but economic deterrents remain. Cost per mile compares favourably with other modes of transport, but cost per hour is enormously higher, and for this reason helicopter services, although technically possible, are unlikely to enlarge the dormitory radius of large cities. International tourism has not advanced because of air travel, for although the time-factor is favourable, the cost remains prohibitive, and total trans-Atlantic travel has not, for example, increased with the possible air speed of the journey. Dr. Warner doubted whether an increase in real income in the higher ranges would be accompanied by a proportionate increase in air travel for personal reasons, such as was the case when the motor-car developed. Drastic reduction in cost or increase in income would be required before inter-continental air travellers could be numbered in millions. Goods, even more than passengers, have to be able to stand high freight-rates by air.

Low costs might promote better inter-continental understanding, assuming it is admitted that the thousands of intra-continental air travellers in Europe have promoted goodwill between their nations. Thousands fly between Britain, France, and the Low Countries, but few go thence as far as Peru or Thailand for personal reasons. But travel is no panacea for world relations. The quality of the traveller will be the measure of its success, and the greater the cultural difference the greater is the need for the understanding which the impact of speed can provide. The disadvantage may be that with greater potentiality of range may come a more superficial knowledge of countries and peoples, to the detriment of understanding. The man on the camel may travel slowly, but he has the time to observe and digest. The antidote is in better education and preparation for travel in order to absorb the lessons to be learned abroad.

The greatest consequence of speedy air travel, however, lies in the transportation of statesmen and functional specialists. It facilitates centralization of an authority covering huge areas. It makes for the mobility of the narrow specialist and the meeting of principals of States. With these men time is at a premium and cost is disregarded. It may be that this creates a tendency to enter prematurely into negotiations and is a debatable asset. Here again it is for man to muster the impact of speed on his side and use it wisely. It could be used for promoting the decentralization of government and population, considered by many to be so desirable, to promote healthy regionalism and disseminate cultural amenities.

Among the indubitable benefits of air transport is the ability to respond quickly to an emergency where peace is threatened, and neutral commissions can quickly attend a trouble-spot while negotiation is possible. Greater use may be made of specialist knowledge with this greater speed and mobility. In business it allows quick personal inspection abroad, quick demonstrations in the field, access to remote markets, and should promote the realization of the need for healthy international trade as opposed to domestic protection. The aeroplane had, however, the misfortune to grow up in an era when States were struggling for autarchy, when its military potential made it suspect, and sovereign rights were jealously guarded. Since 1945, prospects have brightened for co-operation, and the further impact of speed envisaged by Sir Ben Lockspeiser might make a critical difference to the travelling statesman.

In the following discussion Mr. Ritchie Calder, chairman of the Division for the Social and International Relations of Science, suggested that the impact of speed demands a geo-psychology—a study of the impact on world society of high-speed communications—and still further, physiological research into the effect of high speed on the ordinary traveller. He doubted whether the effects of speed, psychological or physiological, on the normal man are understood; he remains tense and strained after a long air flight, and occasionally feels after sudden translation that he has left his 'psyche' behind.

Mr. Calder wondered whether much of the bitterness and rancour of international diplomacy may be attributable to physiological and psychological maladjustment, due to the impact of speed, rather than to political irritability. He wished to have enlightenment on whether the repeated 'breakfast-table crisis' creates either an unhealthy and prolonged nervous tension or an equally unhealthy apathy to international danger. He wished for clarification of the impact of speed. He, too, emphasized the neutrality of science, and pointed out that man's lying propaganda on the air can be even more devastating than his misuse of applied science in destructive weapons.

Historically, crises often die naturally before they can be developed; to-day, each international crisis brings immediate and often dangerous reaction. Mr. Calder fears, too, that speedy communications may be to the detriment of local culture, that a uniform and dull standardized culture may result, devoid of all graciousness and pleasing eccentricity. The white light of universal enlightenment includes in its spectrum the colours of all the cultures of the world. He asked whether we can reasonably impose the impact of speed on primitive societies and offer them our neuroses and physical sicknesses with it; he suggested that one of the most serious problems of scientific men is to discover the impact of speed in world communications upon our society.

Prof. D. W. Bronk, president of the Johns Hopkins University and chairman-elect of the American Association for the Advancement of Science, as a physiologist suggested that the questions Mr. Calder had posed are as yet unanswerable, though he doubted whether the 'psyche' is temporarily left behind on sudden translation from continent to continent. The impact of speed certainly demands of man quick decisions on his day-to-day problems, and a quickening in his mental reactions; but he also made it clear that the essentials for bringing world order from chaos are present if we chose to use them. The same swift aeroplane can bomb an enemy or carry a sick friend to a remote hospital.

Prof. A. V. Hill, president-elect of the British Association, then gave a warning that there is a limit to the rate at which man can accommodate himself to faster travel. On foot, man has improved on the mile running record by 12 seconds, in the same time as he has taken to change from 10 miles per hour to 600 miles per hour flight. The effect of such rapid change is bound to be tiring and inconducive to sustained first-class work. He mentioned that the accelerated process of burning frequently becomes an uncontrollable conflagration, and left his listeners to draw their own conclusions. Isolated wars and isolated diseases may now, with the impact of speed, get quickly into the general circulation with disastrous results. Speed has explosive tendencies and man should inquire into and attempt to control such tendency.

Dr. L. B. Cacciapuoti, deputy-director of the Social Science Department of the United Nations Educational, Scientific and Cultural Organization, winding up, struck a hopeful note, suggesting that the impact of speed will make for the quicker and wider dissemination of scientific knowledge in a manner similar to that following on the development of the art of printing. The impact of speed means that associations of scientific workers may now congregate from the corners of the earth, and with radio communication and air transport, no man of science need find the latest developments or the greatest men inaccessible to him. Such easy access to discuss calmly, with the aim of seeking truth about natural phenomena, promotes fraternal feeling transcending artificial political and racial barriers. Dr. Cacciapuoti's fear is that over-specialization may defeat this end by losing sight of the wholeness of science; but here again he hoped the impact of speed would overcome the difficulty, by spreading scientific knowledge, below technical specialization, but at a high level. He professed great faith in the potential for international association of men of science which the impact of speed on world communications makes possible, and in which he trusted lies the germ of world peace and understanding.

JOHN MACPHERSON

HISTORY OF CULTIVATED PLANTS

A SERIES of papers on cultivated plants, with special reference to their origins and histories, was given in Section K (Botany) of the British Association at the recent Edinburgh meeting.

Sir John Milne Home opened with a discussion of the introduction of exotic conifers into Great Britain and their influence on forestry. Several of these have been long established in Britain; thus, the Norway spruce (*Picea abies*), which is suited to the rainfall, was introduced about four hundred years ago. Other species long known in cultivation in the British Isles include the sitka spruce, Japanese larch, Douglas fir, giant silver fir, western hemlock and the western arborvitæ. More recently many species have been, and are being, given trials; but their value as forest trees in Britain remains more or less uncertain. Included in this category are the Monterey cypress, the Serbian and oriental spruces, two firs (*Abies amabilis* and *A. nobilis*), and the giant redwood. Many of the new introductions thrive well under certain conditions, but have limits to their sylvicultural value. Exotic conifers have had a great influence on British forestry, and this may be increased in the future.

Mr. J. M. S. Potter dealt with the history of the apple. It is not possible to say exactly where the cultivated apple originated; but it spread through Europe from east to west. *Pyrus malus* (*Malus communis*) was certainly one of the most important of its ancestors; but botanists are not entirely in agreement regarding the classification of the subdivisions of this aggregate species. The Romans may have introduced the cultivated apple to Britain. It was widely grown in monastery gardens, and since the monks were in contact with monasteries on the Continent new sorts of apples were frequently introduced. South-east England, from its nearness to the Continent and by the immigration of refugees, became a centre of fruit-growing in Tudor times. Many names of cultivated apple varieties are of French or Flemish origin. The distribution of apple cultivation on a commercial scale in Britain largely depends on ecological factors; dessert apples are mainly grown in drier areas, since fungal diseases can be more easily controlled than where the rainfall is heavy. Turning to more recent times, T. A. Knight may be regarded as the father of fruit breeding. In 1894, Pickering, at Woburn, started the first modern studies on fruit research in Britain, and in the succeeding years three institutions dealing with research in fruit were founded: the Long Ashton Research Station in 1903, the John Innes Horticultural Institution in 1910, and the East Malling Research Station in 1912. Apple cultivation has been revolutionized by studies on rootstocks, fertilizer treatment, pruning methods, general orchard practice, diseases and pests, fertility and sterility, and the breeding of new varieties. It remains to be seen if scientific research will result in the production of varieties better than those left to us by our forefathers.

The subject of olives was considered by Dr. W. B. Turrill, who said that both the wild and cultivated plants are characteristic of the countries bordering the Mediterranean Sea. The cultivated olive is of very great importance to the countries of southern Europe, northern Africa and western Asia for its fruits and the oil produced from these. Before the Second World War the area covered by olive plantations was estimated at 22,580 square miles, yielding 160,000 tons of oil and 20,000 tons of fruit for table use. Spain, Italy, French North Africa and Greece were the largest producers in the order named. *Olea europæa*, the common olive, is an evergreen tree up to fifteen metres in height or a shrub. Its opposite leaves are narrowly elliptic to linear-lanceolate of a subdued green on the adaxial and whitish grey on the abaxial surface. Its small white flowers are produced in May, and the best oil comes from the pulp of the drupes. The tree requires warm, well-drained soil, and responds quickly to proper treatment, especially to pruning. A large number of varieties, based on fruit shape, have been named and described. These are mainly propagated by vegetative means, and the varieties, as with so many other cultispecies, therefore occur as clones. The wild olives of the macchie, usually referred to as var. *oleaster*, are a heterogeneous assemblage, a mixture of microvarieties that need detailed cytogenetical investigation. The two or three published records of chromosome counts give $2n = 46$; but all are based on cultivated material.

About eighty-five species have been described within the genus *Olea*; but recent research shows that many of these are not valid species. The genus is mainly tropical, apart from *O. europaea*, and ranges through tropical and south Africa, the Mascarenes, western China, the Indian subcontinent, Malaya and Australasia. It does not occur in the New World. *Olea chrysophylla*, to which several species have been reduced, has the widest range throughout the greater part of Africa south of the Sahara and in Asia from Afghanistan to western China. In the Sudan and the southern Sahara there are plants intermediate between *O. chrysophylla* and *O. europaea*, and others occur also in Madeira. In particular, specimens named *Olea laperrini* from the Hoggar Mountains and from Jebel Marra are of great interest.

The place, time and immediate ancestry of the cultivated olive are unknown. It is frequently referred to in the Old Testament and in ancient Greek literature. The legends of Greek mythology point to its origin outside Greece and its introduction as a plant already in full cultivation. In ancient Egypt, the olive was certainly known, even in pre-dynastic times, and recent archæological evidence suggests that it was of greater importance than was formerly thought. Unfortunately, there is no known reliable evidence of *Olea* as fossils, and the few cytological studies published throw no light on the origin of the cultivated olive. After a careful consideration of various possibilities, it is concluded that *Olea europaea* may have arisen from *O. chrysophylla* in northern tropical Africa and that it was introduced into the countries of the Mediterranean Basin via Egypt and then Crete or Palestine, Syria and Asia Minor.

In outlining the history of the more important cereals, Dr. G. D. H. Bell pointed out that the chief centres of origin of these are the Mediterranean basin, Persia, Abyssinia, far-eastern Asia, south-eastern Asia, central Asia, and South America. These centres for the most part coincide with areas of ancient civilization. The genera mainly considered by Dr. Bell were *Triticum*, *Secale*, *Hordeum* and *Avena*. The oats are taxonomically quite distinct from the first three of these genera, for which a prototype with $2n = 14$ chromosomes has to be postulated. In the genus *Triticum*, mutations gave rise to various species and were followed by polyploidy. Wheat, however, did not evolve within the one genus. A cross between a diploid *Triticum* and a diploid *Agropyron* followed by allopolyploidy gave the chromosome number of $2n = 28$. A second intergeneric cross between a *Triticum* with $2n = 28$ and an *Aegilops* with $2n = 14$, again followed by chromosome doubling, gave the important wheats with $2n = 42$. Cytogenetical researches on barley and rye have thrown much light on the constitution and origin of these cereals; but the history of cultivated oats is less well understood in spite of the fact that they are of more recent origin than the other plants here considered. The infinite range of morphological and ecological types of the cultivated cereals was emphasized.

Dr. J. G. Hawkes reminded the meeting that the potato was introduced into Europe at the end of the sixteenth century and was regarded as one species until the early part of this century. Now about fifteen species are recognized in place of *Solanum tuberosum*. The basic chromosome number of these is $x = 12$. South Peru and north Bolivia, centres of ancient Andean civilizations, are included in the range of the *Tuberosa* series. Chromosome numbers ranging from diploid to pentaploid occur in the cultivated potatoes and to hexaploid in wild species. Probably wild tetraploids were taken into cultivation. In nearly all areas of western South America there occur wild potatoes with long stolons. These grow in places where competition with natural vegetation is not great and where the soil is rich in nitrogen. Hence they take full advantage of areas disturbed by man. They survive from one season to the next by pieces of the long stolons being left behind in the soil by the early users of the tubers. The original ancestor of the cultivated potato, however, probably no longer exists—it was all taken into cultivation. No doubt the modern potatoes show little resemblance to the first cultivated plants.

ANIMALS AND FORESTRY

SECTIONS D (Zoology) and K* (Forestry) of the British Association held a combined symposium at the recent meeting in Edinburgh in order to discuss the relation of animals to forestry. Dr. F. Fraser Darling, a member of the Scottish Committee of Nature Conservancy and formerly director of the West Highland Survey, opening the symposium with a contribution on mammals, said that the relation of mammals to forest growth is a critical one, for its survival or extinction, and it is one of the most dramatic complexes in Nature. The advent of pastoral, agricultural and civilized man has complicated the situation ecologically. Forests are either climaxes or stages well on the way to the climax, a feature of which is the increasing variety of organic forms and degree of stability. This stability may be interpreted as self-regulation, and the biological system becomes a continuum. Climaxes are constantly being broken by natural catastrophes such as hurricane and fire, but in limited areas, so that the set-back in ecological succession creates edge effects and allows the continued existence of forms which could not endure in the absolute climax. The over-all biological picture is enriched by periodic natural catastrophe.

The profound benign or depressive influence of mammals in the natural chequerboard of climax forest, secondary growth and primary colonization is clearer if the animals are classified according to what they do—predators, browsers and grazers, rodents and insectivores. The predators as a group, of which several species have been lost by extinction, form the insurance company, ensuring the forest as a continuum by controlling the populations of rodents and grazers and browsers. The insectivores share with birds and predatory insects the control of invertebrate populations which tend to depress forest growth. Control is never absolute and no one species is critical; control rests with the complex. The depletion of the predators in the interests of particular forms of land use has endangered the maintenance of old forests and is a grave handicap to the establishment of new ones. Dr. Darling suggested that human ingenuity is not yet equal to controlling small rodents in an extensive habitat, for example, wood mice (*Apodemus*) and squirrels. Their vast numbers and fecundity, their smallness and capacity for evasion are too much for us. A good and varied stock of small carnivores is not only our best insurance but also the cheapest.

The grazers and browsers are comparatively few in numbers, but represent a considerable bio-mass. Although depressive to forest, a low density (the ratio of 1 red deer to 133 acres or thereabout in the Forest of Fontainebleau was cited) may be positively useful. Nevertheless, said Dr. Darling, it is doubtful whether the new artificial forest of Britain can endure the red deer, or even the fallow. Natural forest as a continuum, used by man on a selective felling basis, can accommodate deer with advantage, but not the plantation intended to be clear-felled and replanted. Some North American forests were described, where the upset in natural predation on deer is leading to some serious situations through over-population. The success of Theodore Roosevelt's promotion of the sporting and sentimental status of deer has been immense in the United States, but there is a lag in public opinion between the conditions of scarcity half a century ago and those of the present day when, in a country of much secondary growth, there are probably more deer than there have ever been before. Dr. Darling asked for much more enlightened critical appreciation of forest health, which would make us sensitive to damage in woodlands before situations become irremediable. The animal populations are more flexible than the forest habitat. The deer-forest era in Scotland, which encouraged an artificially high density, was responsible for the slow death of much natural forest. Forest growth in our day needs constant and highly skilled wild-life management, and the woodlands of Britain are not getting it. The wild-life complex is an immanent entity, benign in habitat maintenance if it is in a state of gentle oscillation, but a menace to our own survival if a warped complex begins to oscillate violently and percussively.

Mr. J. M. D. Mackenzie, formerly of the Indian Forest Service, described his work with nest boxes for birds in woodlands in Britain. The 1⅛-in. hole is desirable for many small species, and, though orientation is important, a clear fly-way to the box is more so. A desirable height for small boxes is 5–6 ft.; but the degree of human interference makes a height of 10–15 ft. much safer. There are specific preferences, for example, a concave bottom is essential for woodpeckers, which do not use nesting material. To get optimum numbers of birds (that is, below the level of intra-specific competition) a fifty per cent surplus of boxes is desirable. Spacing is important, not only for the species of birds but also for the size, species-type and age of the woodland. Mixed forest cut on a selection basis carries the biggest and most varied populations, a finding in line with Dr. Darling's remarks.

The employment of nest boxes, said Mr. Mackenzie, can throw light on problems of distribution, in that it would seem that the presence or absence of nesting sites is often crucial when food may appear abundant. The spread of the pied flycatcher is an interesting example in that this is a species on the increase, but one which has occupied some valleys only after the provision of boxes. The flycatchers arrive in Great Britain when other species have already occupied most of the nesting sites. Interspecific competition is real. In 1947, after the hard winter, resident tits using boxes in the Forest of Dean fell from 54 to 20. Migrant flycatchers rose from 39 to 54, doubtless taking advantage of vacant sites.

Mr. Mackenzie's paper, which was accompanied by interesting comparative graphs, showed that the careful use of nest boxes and the results to be obtained from them after a series of years can be useful tools in the hands of the investigator into problems of forest ecology involving the dynamics of avian populations and their insect prey—a field in which there is little certain knowledge at the present time.

Dr. R. N. Chrystal, of the Department of Forestry, University of Oxford, dealt with the role of insects in forestry. He divided the forest regions of the world into those of temperate and tropical regions, indicating that the temperate forests consist of large areas of conifers of various kinds, some pure hardwood stands, such as oak, beech and birch, and some mixtures of conifers and hardwoods, whereas the tropical forests consist mainly of mixed stands of hardwoods of varying types. The insects can be classified into clearly recognizable biological types—defoliators, bud and seed borers, bark and wood borers, and the immense host of predators and parasites which attack the other insects at all stages of their lives. Insect control, indeed, largely rests with the predatory and parasitic Hymenoptera and Coleoptera.

Insect attack on the growing stand is most obvious in the temperate regions and particularly in solid coniferous forests. It is much less severe in mixed conifer–hardwood stands and at a minimum in hardwood areas. Insect attacks on the highly complex mixtures of tropical jungle forests are negligible. Thus, Dr. Chrystal expressed in his own way the principle emphasized by Dr. Darling and endorsed by Mr. Mackenzie, that the climax mixed forest as a continuum can accommodate a vastly richer fauna than the coniferous stand which in Nature is but a successional phase. Dr. Chrystal drove his point home in discussing the plantation forestry which is being established in Britain, in parts of Europe and in the Antipodes. Faulty choice of species may lead to failure through insect attack—for example, silver fir in some parts of Britain and Denmark—and if we see things aright, such attacks should be looked upon as indicators of unsuitability of site rather than an uncomplicated building-up of insect assault. The artificial coniferous plantation is a hostage to fortune from the nursery to maturity, insects becoming pests which are innocuous in the natural forest. The wood wasp *Sirex* is attacking *Pinus radiata* in New Zealand and acts as carrier of a fungus which helps to cause death of the trees. The present laborious method of trapping *Hylobius* and *Hylastes* beetles with fresh pine logs and bark is quite uneoological and must be looked upon as a makeshift until forestry establishment itself adopts ecological principles.

Britain has as yet suffered little compared with some of the coniferous forests of Europe and North America, and the root causes of insect attacks in these places has still to be accurately determined. Hurricanes, for example, favour virulent attacks on the fallen trees by several species of Coleoptera. Human warfare, causing neglect of forest hygiene, must also be considered as a contributory factor in the large-scale attack of bark beetles in the forests of central and southern Europe. Fire damage in the Landes of Gascony has helped to establish the conditions for attack by the spruce bark beetle, *Ips typographicus*. Conversely, killing attacks of bark beetles of the genus *Dendroctonus* increase fire risk. Drought is another predisposing factor to the build-up of beetle attack. The intermixture of aspen and birch with conifers is now recommended in America, and we are gradually reaching the notion in Great Britain that a conifer–deciduous ratio must be determined and put into practice. All would agree with Dr. Chrystal that such a departure from the pure stand would be as pleasing to the eye as it would be some insurance against fire and insects.

Mr. A. B. Duncan, a landowner and member of the Nature Conservancy, discussed birds in relation to forestry and reached the conclusion that they are of little importance. He confessed to a greater interest in forestry in relation to birds, and described vividly the different associations of birds characteristic of different kinds and phases of forests and plantations. From the pipit–wheatear–merlin association of the bare moor, the very young plantation passes to the short-eared owl–kestrel association when voles are the prey, on to the willow warbler–yellowhammer grouping and then the tit–chaffinch–wood-pigeon–crossbill phase. Prof. H. G. Champion, of Oxford, emphasized in discussion that as forestry gets into going order in Britain all these phases will be in evidence, and there should be no impoverishment of the avian fauna by destruction of habitat.

Sir Henry Beresford-Peirse, in summing up, remarked that the fact which crystallized from the symposium was the widely ramifying consequences of interference by man, and that we had much to learn as to how our inevitable continued interference might be wisely done.

SEPARATION OF STABLE ISOTOPES BY ELECTROMAGNETIC MEANS

By W. D. ALLEN

Atomic Energy Research Establishment

DURING the War, the urgent need for large amounts of fissile material led to developments which, under peace-time conditions, would have matured much more slowly, if at all. Among these developments was the electromagnetic separation plant at Oakridge[1], based upon the research and development at Berkeley under E. O. Lawrence. Before the War, the production of ion beams (usually proton beams) of currents up to a few milliamperes was a normal laboratory problem: also the analysis of ion beams in the mass spectrometer, with mean currents of 10^{-10} amp. The production of large amounts of uranium-235, however, can be achieved only by developing much larger currents at high resolution: and the accomplishment of this in the space of two to three years represented a remarkable achievement.

Since the War, some of the plant at Oakridge has been used for the separation or enhancement of a wide range of elements in quantities ranging from one to several hundred grams[2]. At Harwell, a small separator has been operating since 1948 on the separation of milligram quantities of the lighter elements, chiefly boron and lithium. In 1950 a larger plant, based in broad principle on the Berkeley design, began separation. In Denmark, and also in Sweden, two small separators have studied problems chiefly concerned with gaseous isotopes; and in Holland, a medium-sized separator is nearing production.

As regards the description of the American project, some of the fundamental research reports on the ion source have been collected together by Guthrie and Wakerling ("Characteristics of Electrical Discharges in Magnetic Fields." U.S. National Nuclear Energy Series, vol. 1-5); but most of the technical detail is still classified. Some general comments about the quality of the products may, however, be made, together with a description of the types of experiments in which separated isotopes have been used.

Comparison with Other Methods

The performance of the present larger electromagnetic separation plants is that some tens of grams of almost all polyisotopic elements can be separated into enriched isotopes, the enrichment factor of which varies between approximately 20 and 1,000. As compared with other methods, the greatest advantage of this process is its versatility; in effect, the separation can be undertaken in a single stage of any element of which a vaporizable compound can be fed into the ion source. This means that almost all elements, except for a few in the platinum and rhodium groups, can be readily subjected to analysis. The other major advantage of the electromagnetic method is that all isotopes can be collected simultaneously: the range of mass is never very great (calcium, with six isotopes ranging from 40 to 48 has the widest relative spread), so that, provided the system of focusing covers a moderate range of mass, all the isotopes can be collected simultaneously—in theory. In practice, this sometimes involves minor technical difficulties; for the heavier elements, for example, the relative separation of neighbouring isotopes is small, and the close juxtaposition of many collectors is not easy. However, the difficulties are negligible compared with the problems which would be encountered in enhancing, say, some of the intermediate-weight tin isotopes by methods other than the electromagnetic method.

All other major methods of isotope separation which have been put on a practical basis (diffusion; thermal diffusion; electrolysis and fractional distillation; and chemical exchange) depend by contrast on the development of plant in which the enhancement per stage is small but the number of stages is large. Some of the methods have limited versatility; methods of diffusion and thermal diffusion, for example, are generally applicable to elements which have gaseous compounds and few isotopes. In general, however, a special method has to be worked out for each element: chemical exchange for nitrogen, fractional distillation for carbon (as carbon monoxide), thermal diffusion for helium, etc. Once these plants have been set up and developed, however, the running costs are very much less than the costs of producing parallel quantities by electromagnetic separation. Boron, for example, can be separated by electromagnetic methods; but the beam currents are not high, even compared with other elements, in the electromagnetic process, and the costs per gram are very large compared with boron enriched by other methods.

Enhancements

For most applications of separated isotopes, the degree of enhancement (or enrichment) is the most important factor of the separation process. For a two-component system, we define C, the concentration, as the fraction of the isotope compared with the element as a whole; and the isotope ratio as $C/(1-C)$. Then if C_0 is the initial concentration, and C_1 the final, the degree of enhancement is defined as the ratio of the isotope ratios after and before enrichment, that is

$$\left(\frac{C_1}{1-C_1}\right)\cdot\left(\frac{1-C_0}{C_0}\right).$$

Thus, an isotope of initial concentration 10 per cent enriched by a factor 500 has a final concentration of 98·2 per cent; an isotope of natural concentration 1 per cent enriched by a factor of 100 has a final concentration of 50 per cent. For a multicomponent system (several elements have eight isotopes), such a definition is obviously over-simplified; the accurate description of the enriched sample can only be given in terms of a complete isotopic analysis. However, the enrichment factor, defined above, is still a useful criterion of the quality of the product.

In the electromagnetic separations at Harwell and Oakridge, the enhancements are not infinite, and the products are better described as enriched rather than separated. The enhancements for isotopes of large relative mass separation (lithium-6 and -7) are rather more than 1,000; but if the relative mass separation is small, the enhancements are considerably less, and, while they vary widely from element to element, are usually in the range 20–200. There are several reasons for this: they are all bound up with the fact that one is trying to get quantity separation at high resolution, and in general a compromise must be made. On the whole, however, quality counts for more than quantity, and it is better to reduce output in favour of improved enhancement.

Since the enhancement of the average isotope is not infinite, it might be asked why methods of re-cycling once-separated isotopes cannot be employed. This might be reasonably possible with the isotopes naturally most abundant, where the quantities collected can run to the order of tens of grams. The demand for high enrichment, however, usually applies to the rarer isotopes; and the quantities of these available when initially separated are usually insufficient for re-cycling—or, more precisely, the demand does not justify the effort involved.

Applications of Separated Isotopes

The availability of separated isotopes has opened up many lines of study, the chief of which may be summarized under the following headings.

Nuclear physics. The chief applications of separated isotopes are in nuclear physics. Of the various properties of the individual nucleus, the charge, determining the chemistry of the element, is only one; the spin, the electric quadrupole moment of the nucleus, the energy levels, etc., will vary from isotope to isotope of any given element. For the lighter elements, of course, which have relatively few isotopes, a qualitative picture can be built up without separated isotopes, but a complete analysis of individual properties is difficult. With separated or enriched isotopes, however, the properties of individual nuclei can be studied without difficulty; and, since for most of these studies only small quantities are required, the relatively low output of the electromagnetic plant, as compared with other separation processes, is not a serious limitation.

A good illustration is the example of boron. As noted above, boron enriched in boron-10 is widely used as a neutron detector, having five times the sensitivity as a detector containing the same quantity of natural element. The quantities required are relatively large, and would prove very costly to provide by electromagnetic methods. For studies of the nuclear properties of boron, however, films of only some 100 μgm. per sq. cm. are adequate; and, as boron is deposited from the electromagnetic beam without sputtering, targets can readily be prepared for nuclear analysis. The latter property is a fortunate accident, since boron is an active element at high temperatures, and the preparation of boron films by evaporation is difficult. Films made in this way at Harwell have been used in several studies, including the ($\alpha\gamma$) correlation in the reaction ${}^{10}\mathrm{B}(n,\alpha){}^{7}\mathrm{Li}$ [3], the Q-value of the ${}^{10}\mathrm{B}(p,\alpha)$ [4] reaction, nuclear-levels determined in $\mathrm{B}(d,n)$ [5] and $\mathrm{B}(p,\gamma)$ [6] reactions, and so on. The example of boron has been singled out, but it could be amplified by many references to work on nuclear reactions with isotopes of light or intermediate mass. For those elements which have as many as ten isotopes, it would appear that accurate quantitative work will normally be impossible without highly enriched isotopes.

Enriched isotopes are sometimes used in the study of reactions where it is important not only to eliminate competing reactions but also to concentrate a relatively rare isotope. For example, the quantity of lithium salt which can be loaded into a photographic plate is limited; so that, by using lithium enriched in lithium-6 (natural abundance 7 per cent) the study of a reaction such as ${}^{6}\mathrm{Li}(\gamma,n){}^{5}\mathrm{Li}$ is considerably facilitated[7]. Similarly, in recent accurate work on the Q-values of reactions in light nuclei, the use of enriched isotopes magnesium-25 and 26, silicon-29 and 30 (natural abundances 10, 11, 4·7 and 3 per cent respectively) has enabled the intensity to be maintained with thin targets, and the accuracy of experiment thereby held the same as for the abundant isotopes[8].

As regards overall surveys of the properties of nuclides, a study has recently been published of the neutron scattering due to individual isotopes[9]. When the scattering amplitude is plotted against atomic weight, a curve showing quasi-resonance effects is obtained.

Another interesting field for the application of concentrated rare isotopes is the study of weak natural radioactivities. Thus, the products of Oakridge have been used to establish that the natural radioactivity of indium is due to indium-115 [10]; that the natural alpha-activity of samarium is due to samarium-147 [11]; and have promoted several studies in potassium-40 by enriching it from the natural concentration of 0·01 to 7 per cent[12].

Spectroscopic work. Various types of spectroscopic study can be carried out with the aid of enriched isotopes. There are several examples of rare isotopes of odd atomic weight, the study of the hyperfine structure and spin properties of which has been made difficult by the presence of their much more abundant neighbours of even atomic weight. By using the separated rare isotope, the Copenhagen group has studied the hyperfine structure properties of neon-21 and krypton-83 [13]. As regards the even atomic weight isotopes, the availability of enriched isotopes makes possible a detailed study and survey of the little explored phenomenon of isotope shift. Finally, the concentration of individual even isotopes makes possible the availability of better standard wave-length light sources. Thus, mercury and cadmium have been widely used as wave-length standards: mercury has seven isotopes and cadmium eight, so that in both there is broadening of the lines by isotope shift due to the even isotopes and (generally) hyperfine structure for the odd isotopes. Mercury-198 formed by pile irradiation of gold has been for some time used as a light source free from these defects; but other even isotopes (mercury-202) have recently been separated[14], as a more abundant supply, and krypton-84 has been used for similar purposes[15].

Medical applications. The high cost of separation makes stable isotopes too expensive an item for most medical experiments; one application, however, is a promising exception. Natural iron (iron-54, 56, 57 and 58), when irradiated in a pile, produces radioactive iron-55 and 59. Iron-59 has a half-life (46 days) which makes it suitable as a tracer in experiments with human beings; iron-55, while satisfactory for general biological experiments, has a half-life (four years) which makes it a hazard in experiments on humans. Attempts to obtain iron-59 from pile-irradiated cobalt have proved difficult, owing to the high concentration of cobalt-60. If, however, one forms a 'source' of iron-58, from which the exclusion of iron-54 by electromagnetic separation is easy, then the iron-59 produced by pile irradiation can be extracted by a Szilard–Chalmers process, and the bulk of the iron-58, by repeated irradiation, is eventually converted to iron-59. In this way an adequate supply of suitable radioactive iron is made possible.

Superconductivity. Isotopic effects are usually confined to nuclear interactions, but a recent discovery by Serin, Reynolds and Nesbitt[16] has shown a variation in the superconductive transition temperature of mercury with variation in mean isotopic mass. This effect has been confirmed in Britain and in America[17] by using the separated isotopes of tin, and the theoretical prediction, $T \times m^{1/2} =$ constant, has been approximately confirmed. The British results suggest that possibly the exponent of the mass factor is slightly less than ½.

OBITUARIES

Dr. Yoshio Nishina

The death occurred on January 10, at the age of sixty, of Dr. Yoshio Nishina, president of the Scientific Research Institute, Ltd. By his death, the Japanese scientific world lost an eminent leader.

Dr. Nishina was born on December 6, 1890. Graduating from Tokyo Imperial University in 1918, he entered the Institute of Physical and Chemical Research. In 1921 he went to Europe to study at the Cavendish Laboratory, Cambridge, under Lord Rutherford, then at the University of Göttingen, and later at Copenhagen under Prof. N. Bohr. While working in Copenhagen during 1923–27, he published several important papers, such as "Study on *L*-series X-ray Absorption Spectra of the Elements from Sn to W", "Study on the Effect of Chemical Combination upon X-ray Spectra", and "Study on Quantitative Chemical Analysis by X-ray Spectroscopic Method". Collaborating with Dr. O. Klein, he calculated the scattering cross-section of hard X-rays by a free electron and deduced the well-known Klein–Nishina formula in 1928. In November 1928, he returned to the Institute of Physical and Chemical Research by way of the United States and initiated the pioneer work in the fields of cosmic rays and nuclear physics in Japan.

In 1937 Nishina constructed a 27-in. cyclotron to pursue nuclear research. One of his investigations in this field was to assign the elements ruthenium, rhodium, palladium, silver, cadmium, indium, tin and antimony to fission products of uranium and thorium. He showed that uranium-237 is produced from uranium-238 and uranium Y from thorium-232 by the $(n, 2n)$ reaction. The mechanism of metabolism of plants and animals was studied, using radiosodium and radiophosphorus as tracer. In 1944 a 60-in. cyclotron was constructed by which 18-MeV. deuterons could be produced. Nishina flew to Hiroshima and Nagasaki to investigate the effects of the atomic bombs just after the explosion in 1945.

He was also interested in cosmic ray research. He measured the intensity of cosmic rays in 1944 in the Shimizu Tunnel at a depth equivalent to 1,400 m. of water. The continuous measurement of cosmic ray intensity which is still being carried on was started by him in 1935.

Theoretical physics in Japan also owes much to his leadership.

Dr. Nishina was appointed as the first president when the Institute of Physical and Chemical Research was reorganized as the Science Research Institute, Ltd., in 1948. In 1949 and 1950 he visited Copenhagen and the United States as a representative of the Japan Science Council. As president of the Scientific Research Institute, Ltd., as vice-president of the Japan Science Council and as president of the Japan Federation of Unesco Cooperative Associations, his activities were many and varied.

His death is a great loss not only for the rehabilitation of science and technology in Japan but also for her progress in general. KENJIRO KIMURA

Sir Frank Lindley, C.B.

SIR FRANK LINDLEY, who died at Ditchling on August 15 at the age of seventy, spent practically the whole of his working life in the service of the Patent Office, of which he was comptroller-general from December 1932 to September 1944.

He was educated at Brighton Science School and graduated with an honours degree in physics at University College, London. After entering the Patent Office in 1903 he studied law and also found time to take part in student activities at Birkbeck College. When reading for the Bar he was elected Barstow Law Scholar, took a University scholarship in the LL.B. examination, and became a King Edward VII research scholar of the Middle Temple. He became a senior examiner in the Patent Office in 1922, transferred to the Trade Marks side as assistant comptroller in 1926, and succeeded Sir William Jarratt as Comptroller-General of Patents, Designs, and Trade Marks in 1932.

The earlier period of Sir Frank's comptrollership was dominated by the dual tasks of administering the recently passed Patents Act of 1932, which extended the official search for novelty of inventions to general literature, and taking a very active part in the reform of the Trade Marks law which resulted in the passing of the Trade Marks Act of 1938. The later period was dominated by administration of the Patent Office in war-time when, in spite of bomb and fire damage and much devastation, the work of the Office was carried on continuously. During this period he worked unsparingly at settling the terms of licences for working enemy-owned patents and copyrights, and in dealing with emergency legislation in all branches of Patent Office work. After retiring from the Patent Office he acted for two years as scientific adviser to the Appointments Department of the Ministry of Labour and National Service, in spite of failing health. He endured the progress of Parkinson's disease with conspicuous courage and was bravely upheld by Lady Lindley, whom he first met at Birkbeck College and who survives him with a son and daughter.

NEWS and VIEWS

Dr. Elizabeth A. Fraser

With the departure of Dr. E. A. Fraser, the Department of Zoology at University College, London, loses its member of the longest standing. When she joined the Department as a student in 1905 it was headed by E. A. Minchin; but it was under his successor J. P. Hill that she began those original studies in vertebrate development which have been her chief scientific interest ever since. This work has, among other things, contributed much to our understanding of the evolutionary morphology of the excretory organ of the vertebrates, and has provided the basis of our knowledge of the segmental structures of the marsupial head. All her work shows the accuracy and care in minute observation that is an important part of the heritage of classical embryology. With this she combines an appreciation at once sympathetic and critical of the schools of experimental morphology that has served as an admirable stimulus to her many students. Past students of the Department have, indeed, much to thank her for. Whether as assistant, senior lecturer, reader, acting head of the Department (during its war-time evacuation), or since the War as an honorary research associate, she has followed their progress with helpful interest and has never spared herself in their service.

John Kidd, F.R.S. (1775–1851)

John Kidd, who died a century ago on September 17, 1851, studied medicine at Guy's Hospital, London, and in 1801, after graduating, was appointed reader in chemistry in the University of Oxford. He held the Aldrichian professorship of chemistry from 1803 until 1822, when, through the influence of his former teacher, Sir Astley Cooper, he became regius professor of medicine. He was also physician to the Radcliffe Infirmary and, though he had a large private practice, found time for chemical, geological and mineralogical pursuits. He published "The Outlines of Mineralogy" in 1809 and enriched the Ashmolean Museum's collection of geological specimens. A Fellow of the Royal Society, Kidd's contributions to the *Philosophical Transactions* included an "Essay on the Spontaneous Production of Salt-Petre" (1815) and a paper on "The Anatomy of the Mole-cricket" (1825). Elected keeper of the Radcliffe Library in 1834, he supervised the compilation of the section on medicine and natural history of its catalogue. His Bridgewater treatise "On the Adaptation of External Nature to the Physical Condition of Man" (1837) reached its sixth edition in 1852. Kidd's dislike of ostentation led him to abandon the wig, large hat and gold-headed cane, beloved of his medical colleagues at that time.

Nuffield Foundation Grant for Research at King's College, London

It is announced by the University of London that the Court of the University has accepted a grant of £10,000 from the Nuffield Foundation for research in biophysics in King's College under the direction of Prof. J. T. Randall, Wheatstone professor of physics. The grant is available over a period of three years and makes provision for a number of fellowships. The present work of the Laboratory, already supported by the Medical Research Council and the Rockefeller Foundation, is to be extended so as to develop the use of electronic devices in conjunction with ultra-violet and infra-red radiations in the study of cells and the structure of biologically important molecules.

Laboratoires: Bilingual Review of French Technology

A new quarterly review in French and English, *Laboratoires* (No. 1, April–June, 1951; pp. 56; Paris: Laboratoires, 11 rue Tronchet; 400 francs or 1500 francs a year), is devoted to French scientific instruments and technical developments. As Prof. G. Yvon explains in the foreword, the aim of the review is to present an accurate picture of research and technical activities in France to-day, and in this way to enable the world to appreciate more fully the work done by French men of science, technologists and industrialists. The first number contains seven articles by leading French scientific workers and technologists. The first, by L. de Broglie, is a discussion of the position of science in general culture, and this is followed by a description by L. Binet of two series of experiments which serve to illustrate the importance of the use of fish in the study of antitoxins. A condensed version of the first part, dealing with precision in metallurgy, of P. Chevenard's important address on January 15 to the members of the Société des Ingénieurs civils de France is given in the third article. "The Engineer and Technical Research" is discussed by M. Roy, a leading French aeronautical authority; and in an illustrated paper on French optics, by P. Fleury, director of the Institut d'Optique, Paris, the development of optical science and of the optical industry in France is outlined. Finally, the number concludes with two interesting articles: one on the influence of the electrical and electronic industries on the evolution of scientific research, by M. Ponte, director-general of the Compagnie Général de T.S.F.; and the other on calculating machines and human thought, by V. Zelbstein, president of the French association of electronic engineers, in which he maintains that many of the ideas involved in cybernetics date back to Descartes, Pascal and others. The English and French versions of the text are printed in parallel columns. The English translation is on the whole good; but there are, however, several peculiar phrases, mis spellings and too-literal translations.

Activities of the Department of Scientific and Industrial Research

THE Department of Scientific and Industrial Research has issued a "Brief Guide to the Research Activities of the D.S.I.R. and the Research Associations", in which, following an alphabetical list of the research associations and research stations of the Department, research activities are listed by subject according to the Universal Decimal Classification, with an entry indicating the organization or station where the research in question is proceeding. An alphabetical index of the U.D.C. numbers used is supplied. This first attempt to group the activities of the Department according to the subjects concerned helps to fill in the picture of scientific research in Great Britain which was given in the "Notes on Current Scientific Researches" prepared for the Royal Society Empire Scientific Conference in 1948, and which will be supplemented later this year by a companion volume "Scientific Research in British Universities" now in preparation. Copies of the present publication are being made available on request to libraries, research organizations, university departments and industrial organizations (D.S.I.R., 5–11 Regent's Street, London, S.W.1).

Artificial Rock for Display Purposes

IN the July issue of the *Museums Journal*, Mr W. T. Stirling, of the Royal Scottish Museum, Edinburgh, describes two methods of making artificial rocks. One of these is applicable to large exhibits and is built up in sections. After roughly arranging the specimens in position, a permanent wooden framework is constructed. This can be covered with tinned sheet iron of 0·005 gauge. When the structure has assumed the desired shape, which in all cases should be based on a photograph of a natural scene, the tin is covered with irregularly torn pieces of brown paper. These are soaked in hot water—for softened in this way they accommodate themselves readily to the required shape—and then fixed with a mixture of equal parts of flour-paste and thin glue. Smaller exhibits can be constructed in peat, and fine detail obtained easily with the use of a penknife. Loose fibres are singed with a gas flame and the charred surface brushed clean. At this point the two methods coincide, and the prepared rockwork receives a coating of thin plaster made by mixing one part of glue in five parts of boiling water and stirring in plaster of Paris until the mixture is of the consistency of cream. This is applied warm, and well brushed into the rockwork. It is advisable to apply a final coating of a thicker mixture of the above ingredients, or preferably of papier mâché. The rock should then be coloured, paying particular attention to detail.

Dunsink Observatory: Work during 1950

DR. H. A. BRUCK, director of Dunsink Observatory, gives a short account of the work of the Observatory during 1950 in the June issue of the *Irish Astronomical Journal* (1, No. 6; 1951). The chief instrument, the solar installation, has been completed, and the large concave-grating spectroscope has been mounted in its double-walled box the internal temperature of which will be controlled by a thermostat. New photoelectric photometers for the 12-in. refractor and the 15-in. reflector, involving the use of photomultiplier tubes, have been constructed. The reflector, with a photomultiplier photoelectric photometer, the output of which is recorded by an oscilloscope, has been used for precision measurement of the time of lunar occultations, and an occultation can be timed with an accuracy of a hundredth of a second by this method.

Royal Anthropological Institute: Annual Report

THE annual report of the Royal Anthropological Institute is more heartening than has been the case for some years. Finance is still the major worry; but this will ease when the Institute with certain other selected learned societies is housed in the new science centre to be built in London. On January 1 this year *Man* achieved its golden jubilee—a notable achievement for any learned journal. The Institute has decided to set up a blood-group centre as part of its work. Collation and synthesis can probably be best served by such an organization run in association with anthropologists. The library of the Institute has been largely transformed, thanks to a grant of 5,000 dollars from the Viking Fund. The fellowship of the Institute is mounting slowly; but, considering the services rendered, it is surprising that the number of Fellows is not greater.

Manchester Public Libraries: Annual Report for 1949–50

THE ninety-eighth annual report of the Manchester Public Libraries Committee for the year ended March 31, 1950 (pp. 40+4 plates; Manchester: Central Library, 1950), records a reduction in the combined issues of all departments, despite an increase in the use of the reference libraries. The reduction is most marked in the circulation of fiction; within the limits of the present book fund it has been impossible to replace many thousands of volumes withdrawn after very heavy use during and after the War years, and this is regarded as the basic factor in the reduction of total issues from 6,537,939 volumes to 6,124,747, thus interrupting the continuous increase of recent years. While issues in the Reference Library increased by some 3·5 per cent, issues in the Technical Library decreased by 5·5 per cent in spite of an increase of 6·5 per cent in the number of readers using the Library. The demand for more advanced technical books seems to follow supply; libraries which are able to maintain a good range of such works all report that good use is made of them. Stress is laid on the inadequacy of the seating accommodation in the General Reference Library, which is often monopolized by students, while the staff are fully occupied in the routine of providing books for readers and have little time to assist those unfamiliar with the Library or requiring expert assistance. Records of issues in the Technical Library show a transfer of interest from the sciences to the useful arts, and calls on the Technical Library's resources by local firms urgently needing special articles or books increased by 72 per cent.

Nottingham Research Discussions on Engineering Technology

A SERIES of research discussions on various branches of engineering technology, which is being arranged by the Departments of Civil and Mechanical Engineering of the University of Nottingham, will be held at the University during October 1951–May 1952. The meetings will consist of lectures and discussions on topics on which research is being carried out at the University, and the object of the series is to facilitate co-operation between the University and industry. The subjects, which will be discussed on consecutive Wednesday afternoons (2.30–4.30 p.m.) between the dates as shown, are as follows: dynamic properties of metals (October 17–31), fatigue of metals (November 21–December 11), structural analysis and the use of models (January 16–30), use of analogies in fluid mechanics (February 13–20), photoelasticity (March 5–19), and dynamic properties of rubber (April 23–May 7). Admission to the meetings is free. Enrolment forms and further details can be obtained from the Registrar of the University, University Park, Nottingham.

Use of Solid Carbon Dioxide in preparing a Cold Bath

L. G. E. Bell, Department of Zoology, King's College, Strand, London, W.C.2, writes: "Making up a cooling bath by adding solid carbon dioxide to industrial methylated spirit often involves considerable frothing of the spirit unless the addition is made very slowly. I have found that a few drops of a light paraffin sprinkled on the surface of such a bath reduces this frothing very considerably. Three or four drops of cigarette-lighter fuel are sufficient to control a surface of thirty inches square and enable a rapid addition of solid carbon dioxide to be made."

Announcements

With the retirement of Prof. H. Hartridge in May last, the Vision Research Unit of the Medical Research Council has been re-formed as the Group for Research in the Physiology of Vision, under the directorship of Dr. L. C. Thomson. The scope of the work undertaken by the members of the new Group is essentially similar to that of the Vision Research Unit, and the address remains the same, namely, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1.

The Royal Society of Arts has awarded the R. B. Bennett Empire Prize for 1951 to Mr. E. Bruce Levy, director of the Grasslands Research Division of the New Zealand Department of Scientific and Industrial Research, for his work on grassland farming. This Prize, which is worth 100 guineas, was endowed in 1944 by the late Lord Bennett and is awarded every three years for the most outstanding contribution from the Dominions and Colonies of the British Commonwealth to the promotion of the arts, agriculture, industries or commerce.

Prof. N. F. Astbury, professor of applied physics in the New South Wales University of Technology, has been appointed to the chair of physics at the Gordon Memorial College, Khartoum.

The National Conference of the Institute of Personnel Management, which includes the annual general meeting of the Institute, will be held at the Royal Hotel, Harrogate, during October 5–7, the theme being "Personnel Management and Productivity". The Conference will begin at 8.30 p.m. on October 5, and prior to this on the same day a one-day course on "Personnel Management" will be held in the Lounge Hall, Royal Baths, Harrogate. Further details of both meetings can be obtained from the Institute at Management House, Hill Street, London, W.1.

A symposium on the corrosion of buried metals, organized by the Iron and Steel Institute in conjunction with the British Iron and Steel Research Association and the Corrosion Group of the Society of Chemical Industry, will be held at the offices of the Iron and Steel Institute, at 4 Grosvenor Gardens, London, S.W.1, during December 12, with Sir Charles Goodeve, director of the British Iron and Steel Research Association, in the chair. The symposium will be open to all, free of charge. Admission tickets (application to be made before October 13) and further details can be obtained from the secretary of the Institute at the above address.

A second conference on coastal engineering, sponsored by the Southwest Research Institute, San Antonio, Texas, in co-operation with the University of California, Texas A. and M. Research Foundation, Rice Institute, University of Houston and the American Society of Civil Engineers (Houston Branch), will be held at the Rice Hotel, Houston, Texas, during November 7–10. The major topics to be discussed will be the fundamentals of wave action, development of basic design data, natural and artificial movement of sediment, site criteria for harbours and other coastal works, design and construction of structures exposed to wave action, and the biological impact of marine structures. Further information can be obtained from the conference secretary, Charles E. Balleisen, c/o Southwest Research Institute, 8500 Culebra Road, San Antonio 6, Texas.

The Chemical-Biological Coordination Center of the National Research Council is organizing the second Symposium on Chemical–Biological Correlation, to be held at the National Academy of Sciences in Washington, D.C., during October 24–25, 1952, and it is intended to include in the programme one or several scientific films which deal specifically with the effect of chemicals upon biological systems, such as organisms, organs, tissues, cells, etc. Any information about the availability of such films should be sent to the Center at 2101 Constitution Avenue, Washington, D.C.

The second International Congress of Biochemistry will be held in Paris during July 21–27, 1952. The programme has been provisionally arranged in seven sections, as follows: biochemistry of steroids, biochemistry of hæmatopoiesis, biogenesis of proteins, tricarboxylic acid cycles, bacterial metabolism, mechanism of action of antibiotics, protein hormones and hormones derived from proteins. Communications dealing with other biochemical problems will be grouped together in further appropriate sections. Those intending to read papers should send in the titles before March 1, 1952, and a summary of less than two hundred words before April 1, 1952, to the general secretary of the Congress, Prof. J. E. Courtois, 4 Avenue de l'Observatoire, Paris 6^{e}.

The Board of Greenkeeping Research has recently been registered as a public company limited by guarantee under the provisions of the Companies Act, 1948, and will henceforth be known as the Sports Turf Research Institute. The new Institute remains as previously a non-commercial, non-profit-making organization and will maintain the work of the old Board as a research, advisory and educational body in problems of turf (see *Nature*, 166, 22; 1950). The headquarters will continue to be at the St. Ives Research Station, Bingley, Yorkshire.

PROBLEMS OF MARGINAL LAND FARMING

By SIR PATRICK LAIRD, C.B.

Secretary, Department of Agriculture for Scotland

UNDER this title a subject which has attracted much attention in recent years was discussed at the Edinburgh meeting of the British Association in a joint session of Sections F (Economics) and M (Agriculture) at which I had been invited to preside. Before vacating the chair, the president of Section M (Dr. E. M. Crowther) opened the proceedings by posing a question as to the precise meaning of the title. None of the speakers, however, gave an unequivocal answer to Dr. Crowther's question. Indeed, it was pointed out that when it had come to drafting legislation designed to give assistance to marginal land farmers for the rehabilitation of their holdings, nobody would venture to use the phrase marginal land at all; it became 'livestock-rearing land'.

All the papers read and the contributions to the debate did, in fact, accept that the main problems involved are those of the farmers (mostly small farmers) in the upland areas the main productive function of which is the rearing of store cattle and sheep. The chairman pointed out that there are at least three aspects of the problems involved: first, that of the technical agricultural difficulties in the management and improvement of land and stock; secondly, that of the economic and sociological factors affecting the welfare and prosperity of this sector of agriculture; and thirdly, that of the wider economic justification, or otherwise, of devoting national resources to food production on the less fertile land of Great Britain. It is at least arguable that the country would need to use to the utmost both the better and the poorer land.

Prof. W. Ellison, of Aberystwyth, gave a most interesting analysis, based on surveys and investigations in England and Wales and Scotland, of the probable costs involved in the rehabilitation of land and equipment in the upland areas, and of the increased returns which might be expected after the improvements had been carried out. Broadly, it appeared that costs working out at about £32·5 per acre could, over a period of years, be almost exactly recovered in higher returns. In Prof. Ellison's view this would not be attractive without the present subsidies (for liming, drainage, hill cattle, etc.) *plus* the 50 per cent grants for rehabilitation schemes now available under the Livestock Rearing Act, 1951. The money available under this Act, it was pointed out, would probably enable at least one million acres (out of some 3·75 million 'improvable' acres in Great Britain) to be rehabilitated. It was estimated that more than 50 per cent of all improvement expenditure would be on equipment, that is, rehabilitation of the holding rather than improvement of the land.

If *all* the improvable livestock-rearing land could be dealt with on these lines, Prof. Ellison concluded, additional output could be obtained equivalent to between 350,000 and 400,000 store cattle, providing when fattened an extra 100,000 tons of meat. This is rather more than a third of the meat imported from Argentine in 1949 and a little less than Australian supplies.

Mr. O. J. Beilby, advisory officer on agricultural economics in the Scottish Department, emphasized at the outset that while the agriculturist thinks of marginal land as being 'land on the margin of cultivation', the economist thinks in terms of the margin of profitability, and therefore of the farm rather than of the land. He pointed out that it has been roughly estimated that there are some 45,000 stock-rearing farms in Great Britain. They account for about 12 per cent of the acreage of all crops and grass, and support some 23 per cent of the sheep and 12 per cent of the cattle in the country. A sample of 122 such farms in Scotland has shown that cattle account for 24 per cent of the output, sheep 29 per cent, crops 26 per cent and poultry and eggs 15 per cent.

Nearly 60 per cent of stock-rearing farms in Scotland are rented at less than £50 per annum. The sample showed an average net income of £488 per annum (including £272 from subsidies). It appears that if the thirteen larger farms in the sample were excluded, the figure would be only £366 (including £220 of subsidies !).

The basic problem, according to Mr. Beilby, is to increase the earning capacity of the farm unit, by increased size of farm, or greater intensity of production. The former method would reduce the number of farmers: it would therefore raise problems of rural depopulation and, by leading to a more *extensive* system of farming, it might well be inconsistent with the needs of the country for maximum food production.

The sociological problems thus touched on by Mr. Beilby were followed up by Dr. Joseph Duncan in the third paper of the morning. The conditions in which marginal land farming is commonly found—such as high altitude, inherently poor soil, exposed situation, short growing-season, distance from markets—do not make it attractive to farmers with capital, and it is carried on usually with the aid of family labour by small men accustomed to a frugal standard of living. The more enterprising tend to leave such areas, and in the past hundred years there has been in many districts a marked depopulation trend. In such conditions the quality of the social life is bound to deteriorate. The community "tends to become a closed one and to lose variety. A shrinking community sheds its tradesmen and its functionaries".

Very many of the farmers on upland farms do not now earn as much as do wage earners on the lowland farms, and because of this and the social isolation there is a constant drain away of young people, who have, thanks to improved transport, discovered that there are more attractive places in which to live and work.

More capital and larger farms seem to Dr. Duncan to be the best solution of the economic problem, though as an alternative upland farms might be taken over by lowland farmers and run in conjunction with lowland farms. Neither method would, however, ease the social problem; and to ensure the kind of community which would solve that problem, it seemed to Dr. Duncan that forestry is essential; there is no good reason why farming and forestry should be regarded as competitive, and on the social side, forests offer more hope of a re-integration of community life in the uplands than anything else.

In opening the general discussion, Mr. A. R. Wannop, technical development officer in the Scottish Department, stressed the importance of maintaining the necessary interdependence of lowlands and uplands as regards both cattle and sheep. He thought we should be careful not to over-capitalize the upland farms, and pointed out that expenditure on the scale suggested by Prof. Ellison might add £2–£3 per cwt. to the cost of production of a weaned suckled calf. There is great need, he said, for a new building technique to cheapen the costs of rehabilitation. A self-feeding pit silo, as used in America, would be a boon. Above all, greater attention should be given to advisory work, directed more to the economy of the whole farm than to details of land improvement.

Mr. Phillips Price and Mr. Gorrie (Ceylon) took up and supported Dr. Duncan's plea for afforestation. As Mr. Price pointed out, Nature abhors continuous cropping, and lack of balance is just as detrimental in the case of livestock as in cultivation. Mr. Gorrie spoke of the benefits derived from the shelter belts established in the eighteenth century, and suggested that progress in the upland areas is dependent on the supply of labour and machinery.

Three or four farmers, from both sides of the Border, made useful contributions to the debate, in which varying views were expressed as to the economics of the business. Mr. J. A. Symon, formerly chief inspector of the Scottish Department, thought that too much attention is paid to that aspect and referred to the go-ahead enterprise of some farmers in the reclamation of land in Orkney and elsewhere.

Perhaps the question still remains: What exactly is marginal land? I am tempted to quote from a delightful little 'essay' written in the early 'forties by a member of a war-time executive committee in the Border country:

'Marginal land was discovered by the Farmers' Union in 1940. Prior to that date there was none of it: to-day there is little else but. The Department, later, recognized its existence. They have regretted their action ever since. Nobody quite knows where it is except the man who farms it. But Members should be suspicious of any land situated near a margin. Such land is almost certain to be marginal land.

"Sub-marginal land is found under marginal land. Sub-soil is not the same thing. Super-marginal land was also discovered on the same day by the same explorer. All land situated above marginal land is super-marginal. These sub and super discoveries should greatly simplify the work of Members."

However, this member and his colleagues, and those of other executive committees in Scotland, have done a good and conscientious job during the past eight years in the administration of the Marginal Agricultural Production Scheme. There are undoubtedly long-term problems still to be solved, but at least these upland farmers, contributing some 10 per cent of the total agricultural output of the country, have been enabled with State assistance to keep going and to make a reasonable contribution to the nation's food supplies.

HIGHER TECHNOLOGICAL EDUCATION IN GREAT BRITAIN

AT a discussion on higher technological education on August 13 before Section L (Education) at the British Association meeting at Edinburgh, over which Sir Hector Hetherington presided, Mr. H. J. Cull gave a well-balanced and concise review of the technical colleges and their development and an appreciation of the contribution they could make in this field. He claimed that higher technological work is a natural part of the development of these institutions, as is indicated by the growth and success of their work in providing courses for Ordinary and Higher National Certificates and for external University of London degrees, as well as, in the larger colleges, for general science degrees, special science degrees and engineering degrees. A technological course of degree standard is a natural development if the needs of industry are to be met, and such a course should include more fundamental science than is usual in National Certificate and diploma courses, and more applied science and technology than finds a place in the external degree syllabuses. If liaison with industry is maintained and developed, the colleges consider that they could provide courses which, with the freedom of an internal examining system, could well be different from the external degree.

Mr. Cull emphasized here that periods of full-time study would be necessary, but that with the co-operation and goodwill of industry there should be no major problem in planning the association of study with experience as a vital part of the course. On the question of the award to be received by the successful student, Mr. Cull indicated the alternative proposals, but urged that early decision is imperative and that any award should carry national recognition. Post-graduate training, he thought, would present less formidable problems if such schemes were allowed to develop, and particularly if the postgraduate courses were developed in association with neighbouring universities. Here, particularly, questions of accommodation and of staff, in his opinion, are important, and equipment and apparatus are expensive items; on the staff side, quality is as important as numbers, and to obtain staff of the requisite quality with real experience of industry and its needs is not easy. He thought that, if properly used, the scales of the recent Burnham report give scope for such appointments to be made. Solution of the problems of accommodation of staff would, moreover, permit the gradual establishment of real centres of research, with teams of research workers, including staff and students, and possibly, in some problems, some workers on a part-time basis from industry. Many of the problems investigated might conceivably come from industry itself, and just as some industrial firms find themselves touching the field of fundamental science, so some investigations in the technical colleges might be concerned with direct industrial problems.

Mr. Cull recognized that not every technical college could or should be called on to provide higher technological courses, and that some regional planning would be necessary. He recognized, too, the critical importance of finance, though he passed over the question of local administration in relation to the academic freedom of the teacher and investigator. He was confident, however, that the technical colleges could provide not only the technicians but also the technologists needed in Great Britain, and that there is in the colleges the enthusiasm to do this work once it is given direction and the student the necessary incentive.

Prof. J. C. Prescott, dealing with the university aspect of the problem, distinguished at the outset between two schools of thought: one regards higher technological courses as providing an opportunity of treating specific advances in technology; the other advocates courses in which the emphasis is upon fundamentals and in which recent technological developments appear as illustrations of the more general theory. In the universities, the mode of study is to approach the particular example by way of the most general principle, to consider specific phenomena in terms of, and by the light of, fundamental theory. This method is in general followed in their schools of applied science, and accordingly, Prof. Prescott suggested, universities could provide the proper environment only for the second type of course. If they attempted to do more they would forsake their legitimate function.

Prof. Prescott pointed out in passing that the rapid advances in technology have created teaching difficulties for the universities, where reorganization to allow greater attention being given to the study of the fundamental sciences has left less time available for the study of their application in technology. Nevertheless, he thought that university courses which first of all establish the fundamental principles upon which technology is created and then show their application by examples selected from among modern developments would provide a satisfactory solution. While a better medium of education from the point of view of technology, they could not be so comprehensive as regards new advances as the courses which they replace. Advanced courses in technology should be regarded by the universities as the natural continuation of their undergraduate courses. Even here, however, the university should be circumspect and insist that the courses approach the particular through the general, and seek to educate rather than to instruct. He did not believe that a university could usefully conduct courses containing little more than an isolated description of recent developments in technology.

Prof. Prescott said that the results of postgraduate courses of the type he advocated, so far as he has seen them, have been excellent. He thought there is no evidence that the courses have had any narrowing effect, because a systematic study of the sciences involved is as essential as their informed and logical application in the technology. Moreover, the increasingly sympathetic understanding of the engineer's outlook by the scientific worker, strengthened by the latter's growing reliance on the engineer for the design of special apparatus, has largely dissipated fears that such courses might turn promising engineers into indifferent physicists or chemists. Indeed, this clear understanding between the engineer and the scientific worker is fostering happier relations between pure and applied science departments in the universities. Higher technological education, in fact, offers the universities, and particularly their faculties of applied science, a great opportunity of giving systematic education to an advanced standard in subjects which in the past they have only been able to treat sporadically, or at a comparatively elementary level.

Neither of these papers gave any attention to the quantitative aspect of the question, on which clearly a decision as to where the expansion of facilities for higher technological education should take place must partly depend ; nor did the ensuing discussion, which was opened by Sir Arthur Fleming, give any clearer lead there, or as to the desirability of any new award. Sir Arthur, commenting on industry's need for the technologist as well as the technician, observed that the number of corporate members of the great engineering institutions who have qualified through National Certificate courses is about the same as the number from university degrees. He endorsed what had been said as to the necessity of teaching of the highest order and the value of postgraduate courses, but added that the chief anxiety in recruitment is as to whether we are securing men of the right type for industry. Sir Arthur urged that the personal qualities of courage, powers of decision, judgment, leadership and the ability to mix well with others should count as much or more than technical or scientific ability. These personal qualities are formed before the young men reach industry, and he knew of firms which for this reason are turning to the public schools, because the technical knowledge could be imparted.

The importance of personal qualities was equally stressed by Wing-Comdr. T. R. Cave-Browne-Cave, who commented that the same qualities of leadership and decision which the Fighting Services seek are needed in industry. The syllabuses of courses should not be so full as to require a concentration on academic work which hinders the development of personal qualities. He thought, too, that it is important for higher technological education to develop independently of the universities, and that the technical colleges should not depend on the universities for their higher award.

The discussion, on the whole, was disappointing in that, although attention was directed to the main factors on which the expansion of technological education in Great Britain turns, no clear lead was given as to their relative importance or the form in which that expansion should immediately proceed. The need for early decision was rightly stressed ; but even in the emphasis on the importance of personal qualities, no suggestions were advanced as to whether these would be better fostered in the universities or in the technical colleges. Sir Arthur Fleming's suggestion regarding travelling fellowships relates to the postgraduate stage and the acquiring of the experience and outlook required to fill the highest positions in industry.

CATALYTIC CONVERSION OF A DIENE INTO DEEPLY COLOURED POLYENES

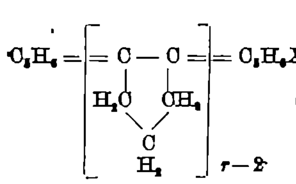
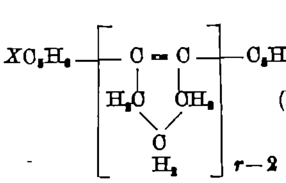
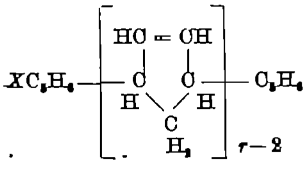
PROPERTIES indicating the presence of conjugated double bonds. *Cyclo*pentadiene can be converted catalytically into a deep red poly*cyclo*pentadiene-trichloroacetic acid adduct (I), the yield under suitable conditions being more than 90 per cent of the theoretical amount. Analyses, molecular weight determinations and fractional precipitation tests make it probable that a mixture of polymer homologues, of composition $(C_5H_6)_r(XY)$ and a number average degree of polymerization $r = 18 \pm 2$, is formed, (XY) being here and later the symbol for trichloroacetic acid. The unsaturated nature of (I) is shown by its large consumption of potassium permanganate, under relatively mild conditions ; and the interaction with molecular oxygen, ozone, nitric acid, perbenzoic acid and hydrogen, in presence of



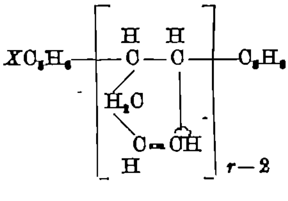
(Ia)



(Ib)



(Ic)



(Id)

platinum oxide, proves that there is one double bond in each *cyclo*pentadiene unit. The deep red colour of the chromatographically purified substance (I), the formation of deeply coloured blue molecular compounds with strong acids, or antimony trichloride, and their decomposition by proton acceptors is compatible with (Ia) or (Ib) rather than with (Ic) or (Id)[1].

The supposition that this polymerization involves a migration of hydrogen atoms with formation of conjugated double bonds is supported by the fact that compound (I) is capable of forming an addition product with maleic anhydride and by its infra-red absorption spectrum in the range of the double-bond vibrations. It has been observed, moreover, that on addition of dry trichloroacetic acid to a solution of compound (I) in carefully dried benzene, with the formation of a dark blue molecular compound, the specific conductivity (which at a given concentration of (I) is approximately proportional to the trichloroacetic acid concentration) shows a marked increase; this indicates salt formation, due to the transfer of a proton to the molecule containing the conjugated double bond[2].

In dilute solution, each *cyclo*pentadiene unit of (I) consumes two bromine atoms. A polymer of composition $(C_5H_6Br_2)_r(XY)$ could not be isolated, however, because hydrogen bromide is lost with great ease and a stable derivative is formed the approximate formula of which is $(C_5H_5Br)_r(XY)$. This product is deep red, like (I); this is probably due to the re-formation of some conjugated double bonds.

Light absorption. Long-chain conjugated polyenes are known to be characterized by sharp absorption bands in the near ultra-violet and visible region[3]. In contrast to this, a band structure in the spectrum of (I) could only be observed between 2500 A. and 2800 A., while in the range 2800–10,000 A. the extinction coefficients decrease continuously; and there are also no bands due to electronic transitions between 10,000 A. and 30,000 A. Account must, however, be taken of the fact that (I) is a mixture of homologues, not an individual conjugated polyene, and it is reasonable to assume that the lack of bands at wave-lengths larger than 2800 A. is due to the fact that the light absorption of the individual components is modified by optical superposition. This hypothesis is supported by the results of experiments (to be described elsewhere) dealing with the light absorption of artificially prepared mixtures of authentic polyenes, containing respectively four, six, eight and ten conjugated double bonds.

Kinetic measurements. These show that the conversion of *cyclo*pentadiene into compound (I) is a chain polymerization involving intermediates of short life-time, and that the course of the reaction can be adequately represented by three elementary steps, namely, initiation, propagation and termination; so far, no indications of chain transfer or marked effects due to traces of water have been observed. The initial rate of the monomer consumption in carbon tetrachloride solution is proportional respectively to the first power and to the square of the *cyclo*pentadiene and trichloroacetic acid concentrations; and the number average degree of polymerization does not depend on the initial concentration of the reactants or on the degree of conversion, up to 80 per cent reaction. These observations can be interpreted by the following initiation reaction involving the trichloroacetic acid-catalysed addition of trichloroacetic acid to *cyclo*pentadiene, and by a termination stage in which the growing polymer reacts with monomer:

$$C_5H_6 + 2(XY) \rightarrow C_5H_6(XY) + (XY).$$

It has previously been found[4] that the rate of the trichloroacetic acid-catalysed dimerization of *cyclo*pentadiene is proportional to the first power of the trichloroacetic acid concentration. If, therefore, the catalyst concentration is sufficiently low, the formation of compound (I) is completely overshadowed by the dimerization reaction. Proton acceptors inhibit both the polymerization process and the catalysed reaction leading to the dimeride[4], and it is probable, therefore, that both processes involve ionic intermediates. It is recognized, however, that the mode of linkage of the *cyclo*pentadiene units in di*cyclo*pentadiene and in compound (I) is fundamentally different, the former substance being the product of a 1:4–1:2-addition[5], which does not involve the migration of hydrogen atoms.

The end group. It is known from previous investigations[6] that trichloroacetic acid adds readily to isolated or conjugated double bonds to form esters. By analogy, it is probable that the initiation reaction already indicated also leads to an ester and that, therefore, the end groups X and Y in compound (I) are respectively Cl_3CCOO and H, rather than Cl_3CCOOH and Cl. This conclusion is in concordance with results of experiments showing that compound (I) is not capable of forming pyridinium, potassium, sodium, calcium, barium, copper or silver salts: and it is proved by the fact that alkaline hydrolysis of (I) gives rise to the formation of alkali trichloroacetate (identified by conversion into the benzyl*iso*thiourea salt), and of a chlorine-free polymer without liberation of chloride ions. If, on the other hand, compound (I) contained a free carboxyl group, the removal of chlorine from the polymer by alkaline hydrolysis would liberate three equivalents of chloride.

Colloid chemical effects. Solutions of compound (I) in benzene are strongly associated; this follows from a comparison of cryoscopic and end-group molecular weight determinations. If the benzene or carbon tetrachloride solution is shaken with aqueous solutions of salts, acids or bases, stable and remarkably viscous emulsions are formed.

A detailed account of this work and the results of similar experiments dealing with other molecular compounds, halogenoacetic acids and dienes will be published elsewhere. We are grateful to Drs. H. Steiner and E. T. Borrows for discussions, to Dr. A. Elliott for some of the infra-red absorption measurements, and Dr. Rubin and Mr. Street for experimental assistance.

PAPER CHROMATOGRAPHY OF MUSCLE TISSUE CONSTITUENTS

Paper Chromatography of Adenosine Phosphates

CARTER[1] has devised a method for paper chromatography of adenosine phosphates. He uses as solvent a 5 per cent dibasic sodium phosphate solution and *iso*-amyl alcohol. For developing the spots after drying, he sprays the paper with fluorescein and localizes the spots with an ultra-violet lamp ('Mineralight').

We have modified the partition coefficient between the two phases by using a solution of 0·5 per cent lauryl amine in *n*-amyl alcohol instead of *iso*-amyl alcohol. The resolution of the spots has much improved by this method. We believe that this method can be adapted to other substances; thus, for substances of basic character laurylic acid can be used to improve the resolution.

We have compared our method with the original method of Carter on adenosine phosphates. With Carter's method, using an adenylic acid preparation (Merck), two spots were obtained with R_F 0·73 and R_F 0·66, and, according to Carter, who obtained identical results, identified as the adenosine-2-phosphate and adenosine-3-phosphate. Besides these substances, a smaller spot due to inosinic acid was visible. Adenosine diphosphate obtained by splitting adenosine triphosphate with myosin gave a longer spot, which sometimes seemed to consist of two spots of R_F 0·80 and 0·75. Adenosine triphosphate from muscle gave only one spot (R_F = 0·82), but often this was somewhat extended.

Using our method, we obtained the following components from the adenylic acid preparation, which tentatively have been identified as follows:

Substance	R_F
Inosinic acid	0·86
Adenosine-2-phosphate	0·69
Adenosine-3-phosphate	0·61
Adenosine	0·48

The component with R_F 0·69 has the same R_F-value as adenosine-5-phosphate, which can be obtained from muscle adenosine triphosphate by cautious hydrolysis or prolonged storage. The components have been identified from the discussions given by Carter[1] and Kornberg[2].

Adenosine diphosphate here clearly showed two spots with R_F 0·76 and 0·69 respectively. The first one is due to the diphosphate; the other one is adenosine-5-phosphate, probably obtained through a small contamination of the myosin by myokinase.

Even adenosine triphosphate from muscle gave two spots, R_F 0·83 and 0·76. The first one is due to the triphosphate, the other to the diphosphate. Adenosine triphosphate is apparently very often contaminated with adenosine diphosphate owing to the instability of the triphosphate.

Our examples show that the modification of the partition coefficient with lauryl amine in amyl alcohol very much facilitates the resolution of the different derivatives of adenosine phosphatos, and is superior to Carter's original method.

A Phosphate-absorbing Protein from Muscular Tissue

IN connexion with the preparation of myosin from cardiac muscle[1], a protein containing a nucleotide has been isolated. This protein seems to be firmly bound to the actomyosin complex. However, it is freed to a certain extent when the complex is dissociated into myosin and actin. Only by treatment with organic solvents has it been possible to separate the protein from undissociated actomyosin.

The interesting feature of this substance is its ability to absorb the phosphoric acid residue, which is split from adenosine triphosphate by the enzymatic action of myosin.

The protein is not myosin. It more resembles actin, but it is not an actin in the usual sense. It does not polymerize and does not combine with myosin as actin does.

The present communication records an attempt to analyse the prosthetic group of the protein. This has been done mainly with the aid of paper chromatography and measurements of the ultra-violet absorption spectra in a Beckman spectrophotometer. The absorption curves have a maximum at 260 mμ in neutral and alkaline solutions. In acid solutions a maximum at 263 mμ is obtained, and here also the curve becomes asymmetric. This is different from that of adenylic compounds. Chromatographic measurements[2] by the method described elsewhere show that the preparations contain not more than two components, or sometimes only one. In the system 5 per cent dibasic sodium phosphate – 0·5 per cent lauryl amine in amyl alcohol, it gives an R_F value of 0·67. In some cases a double spot is obtained with R_F 0·63 and 0·67.

After hydrolysis (0·1 *M* hydrochloric acid, 30 min. at 100° C.) two components appear in the chromatograms. One of these, with R_F 0·40, is identical with adenine, while the other, with R_F 0·85, has not yet been identified. This component seems to be some pyridine or pyrimidine derivative with basic properties. A prolonged hydrolysis causes no changes in this component, and furthermore the chromatographed substance is soluble in acids only. Milder hydrolysis (alkaline hydrolysis or 0·1 *M* hydrochloric acid, 5 min. at 100° C.) gives, in addition to the two spots of R_F 0·40 and R_F 0·85, two other spots with R_F 0·57 and R_F 0·68. The former of these may be adenosine-3-phosphate and the latter probably adenosine-5-phosphate. The component with R_F 0·68 may also be unhydrolysed nucleotide. Extraction of the spots and identification by ultra-violet absorption measurements has not been successful, since the amyl alcohol used in the chromatography is contaminated by a substance with absorption in this region. Purification of the amyl alcohol has been unsuccessful, and it has not yet been possible to get a synthesized amyl alcohol.

These investigations show that the prosthetic group is a dinucleotide. Kornberg[3] has shown that diphosphopyridine nucleotide (co-zymase, co-enzyme I) can undergo a direct phosphorylation to triphosphopyridine nucleotide (co-enzyme II) by adenosine triphosphate and a yeast enzyme. Since the dinucleotide described here has the same characteristic, one may suppose an analogous structure. However, it does not seem to contain nicotinic amide but another as yet unidentified substance with basic properties.

Further investigations are going on, and a more detailed description will appear elsewhere.

The investigation is being supported financially by the Swedish Natural Science Research Council.

The Prosthetic Group of Actin

A STUDY of the prosthetic group of *G*-actin and *F*-actin has been made with paper chromatography, using as solvent an aqueous solution of 5 per cent dibasic sodium phosphate and a solution of 0·5 per cent lauryl amine in amyl alcohol as described elsewhere[1]. We could detect only one spot when investigating the prosthetic group of *F*-actin, the R_F value of which was 0·67. From *G*-actin also only one spot was visible, with the R_F value 0·64. These R_F values correspond to the values found for the phosphate-absorbing protein derived from the actomyosin complex reported in another communication[2]. Acid hydrolysis of the prosthetic groups from the two kinds of actin showed, upon paper chromatography, identical spots with the R_F values 0·40 and 0·85 respectively. The prosthetic group of actin is a dinucleotide containing adenosine and another hitherto unidentified base. This dinucleotide can occur in two forms, one richer in phosphorus (in *G*-actin) and the other poorer in phosphorus (in *F*-actin). It may be mentioned that in no circumstances have any spots derived from adenosine tri- or di-phosphate been detected. The R_F values for these substances under the same conditions are 0·83 and 0·76, so they must occur in insignificant amounts.

Earlier, Straub *et al.*[3] have found that actin contains a prosthetic group which they consider to be adenosine triphosphate in *G*-actin, and which during the polymerization of *G*-actin to *F*-actin splits off one phosphoric acid residue and is transformed into adenosine diphosphate.

The absorption spectrum of the isolated prosthetic group in a Beckman spectrophotometer gives a curve which resembles that of an adenosine derivative. The relation of the absorption curve to *p*H, however, is different from that of an adenosine phosphoric acid. It seems also that the prosthetic group can in certain circumstances be split, giving off adenosine-5-phosphate, which can be deaminated by Schmidt's deaminase. These results have supported the incorrect assumption that the prosthetic group is adenosine triphosphate instead of the dinucleotide.

G-actin contains the dinucleotide which is rich in phosphorus, and *F*-actin contains the dinucleotide poorer in phosphorus. During the transformation of *G*-actin into *F*-actin, the phosphorus-rich and therefore more labile dinucleotide gives off one phosphoric acid residue and is transformed into the dinucleotide of *F*-actin.

Upon contraction *in vitro* of actomyosin with adenosine triphosphate, the myosin splits off a phosphoric acid residue of the triphosphate. It is possible for the energy-poor dinucleotide in *F*-actin to take up such a phosphoric acid residue in the nascent state. *F*-actin is thus transformed to *G*-actin during the contraction.

Straub *et al.* have found that when *F*-actin is dialysed against a solution of adenosine triphosphate for a longer time, the *F*-actin is converted into *G*-actin. At the same time adenosine triphosphate disappears and adenosine diphosphate appears. He assumes that the diphosphate in *F*-actin takes the place of triphosphate. From our results the process is better explained by assuming that the dinucleotide takes up a phosphoric acid residue from the adenosine triphosphate on account of its instability; it always loses phosphorus gradually with time. We have also found that the dinucleotide can take up phosphoric acid residues given off by the adenosine triphosphate in such a manner.

It seems thus that adenosine triphosphate does not play the dominant part previously assigned to it in the contraction process. This role may be taken by a dinucleotide (one group of which is adenosine, the other is not yet identified) which can take up and give off a phosphoric acid residue. The adenosine triphosphate acts as a phosphorus donor.

In many respects this dinucleotide resembles cozymase, which also occurs both as a phosphorus-rich and a phosphorus-poor compound (co-enzyme II and I). A comparison of the dinucleotide with cozymase has shown that they are not identical.

Further details of these investigations, which were supported financially by the Swedish Natural Science Research Council, will be given elsewhere.

CHEMISTRY OF CANCER

A MEETING, under the joint auspices of the Chemical Society, the Royal Institute of Chemistry, the Society of Chemical Industry, and the Institute of Petroleum, was held in Manchester on March 15, with the general title "The Chemistry of Cell Division". The proceedings were sadly interrupted by the sudden death of Prof. G. A. R. Kon while contributing to the discussion at the end of the morning session, and the meeting was abandoned. Three papers were, however, read.

In his introductory survey, Prof. A. Haddow dealt with the biological effects (tumour-inhibitory, cytological and carcinogenic) of cytotoxic substances, with special reference to the nitrogen mustards. It is difficult to improve on the activity of *bis*-β-chloroethylamine (HN2), but *bis*(β-chloroethyl) β-naphthylamine (R.48) has certain advantages and its clinical effects were discussed in some detail. In the case of cancer-producing compounds earlier studied, there is still no knowledge of their exact site of action in the cell. However, the carcinogenic nitrogen mustards, first investigated as potential war gases, and related compounds appear to act directly on the chromosome structure and in so doing bring about effects in many ways indistinguishable from those due to X-rays.

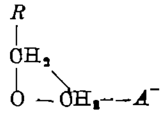
Tumours induced by injection or feeding of these compounds have cytological abnormalities which persist through many generations of transplantation in certain tumours, but which, in other tumours, vanish after a few transplantations. While these observed cytological effects are almost certainly not those primarily responsible for the induction of cancer, they can be regarded as associated phenomena. Chemical features of the nitrogen mustards have suggested the examination of related types of compound such as ethylene oxides and imines, which are of interest on account of their capacity for chemically cross-linking textile fibres and which have been shown to produce similar cytological effects. All these types are believed to react by a carbonium-ion mechanism with reactive centres in protein and nucleo-protein. From studies of the action of such compounds on chromosome organization, Prof. Haddow suggested that the production of cancer in these cases is due first of all to their chemical combination with hereditary material in the cell, and secondly to resultant change in chemical and genetic properties expressing itself as alterations in growth behaviour.

Dr. W. C. J. Ross then delivered a paper entitled "Cytotoxic Action in Relation to Chemical Reactivity" in which he elaborated the carbonium-ion reaction mechanism of radiomimetic cytotoxic compounds. These compounds include sulphur and nitrogen mustards, methylolamides, epoxides, ethyleneimines and some sulphonic esters. All these types can be regarded chemically as alkylating agents.

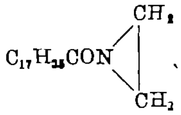
In the case of the β-chloroethylamines, the carbonium ion is produced either by elimination of the chlorine atom as chloride ion under the electron-repelling influence of the nitrogen atom, or alternatively via the cyclic ethyleneimonium ion, which, though reasonably stable in aliphatic mustards, would not be expected to be stable in aromatic analogues. In the case of the ethylene oxides and imines and the sulphonic esters, the reaction is bimolecular, the ion having no separate existence. Thus, for example, the reaction of an ethylene oxide ring with an active centre involves the displacement of the oxygen atom from the reacting carbon atom with the formation of the transition complex (I).

The ease with which various groups react with carbonium ions has been investigated in detail, and in protein the most reactive centres are the ionized carboxyl group followed by terminal and histidine amino groups; in nucleic acids the reaction occurs preferentially with phosphoryl and aromatic-type amino groups. No reaction takes place, at physiological *p*H, with aliphatic hydroxyl groups.

Dr. Ross showed the influence of structure on the activity of the mustard type of compound by an examination of a series of *bis*-(β-chloroethyl) anilines. If electron-repelling groups are introduced into the nucleus, separation of the chlorine atoms as ions is facilitated, reactivity, as measured by rate of hydrolysis in aqueous acetone, is increased, and so is tumour-inhibitory activity. Electron-attracting groups have the converse effect. Similarly, replacement of the chlorine atoms by bromine or iodine, or introduction of β-methyl groups into the chloro compound, leads to enhanced activity in certain weakly active substances. Increasing the separation between active centres in this type of molecule seems to lead to decrease in biological activity, though chemical reactivity is not appreciably affected.



I



II

In presenting his paper entitled "Cytotoxic Action in Relation to Molecular Shape", Dr. F. L. Rose dealt with the role taken by the whole molecule of the cytotoxic agent (as distinct from the formation of chemically reactive centres discussed by Dr. Ross). He showed that not only may the methylolamides, epoxides and ethyleneimines react with cell components, but, in addition, as they are all groupings which are known to lead to polymer formation, polymeric molecules may be the ultimate units which react in the cell. The nitrogen mustards can be regarded as a special case of the ethyleneimines, and a linear polymer with quaternized nitrogen atoms is a possibility.

As a corollary it follows that the activity of certain other cytotoxic agents such as the polycyclic hydrocarbons and the dimethylaminoazobenzenes and stilbenes can be explained on a similar basis, by supposing that the 'polymer' units are made up of micelles or bundles of molecules held together by residual valency forces, each individual molecule being linked by conjugation to cell protein. Certain dyestuffs containing azobenzene or stilbene nuclei are known to have micelle-forming properties, and the large flat polycyclic hydrocarbons may well behave similarly.

This hypothesis has been tested by preparing and examining a long-chain aliphatic hydrocarbon molecule which carries a group capable of reacting with protein and which by virtue of its long chain also forms micelles. This compound, stearoyl ethyleneimine (II), shows cytotoxic action and is a potent carcinogen.

In his introduction to the discussion, Prof. Kon stressed the satisfactory correlation between cytotoxic activity and the degree of purely chemical reactivity of the nitrogen mustards as measured by hydrolysis-rates. On the question whether the effect of chain-length can be attributed to steric or to polar factors, the answer seemed to him to be fairly clear, namely, that the two ends of the chain can be separated within limits, but that if the distance of the terminal carbon atom from the nitrogen atom is much increased beyond two carbon atoms, the activity falls off sharply, as does the rate of hydrolysis. If, however, this separation is achieved by inserting CH_2-groups between two nitrogen atoms so placed as to exert their polar effect and favour the production of a carbonium ion, the lengthening of the chain effects but little decrease in biological activity. Prof. Kon said that he had every hope from all this work of eventual results with a very positive bearing on the cancer problem as a whole.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Localization of Bacterial Nucleic Acids and Mechanism of the Gram Reaction

As a consequence of the brilliant studies of Stacey and co-workers, reviewed by Webb[1], many investigators of the Gram reaction in bacteria are agreed that the Gram complex is a combination of basic dye and pentose nucleoprotein, apparently localized at or in the cell wall. However, as Lison[2] has pointed out, the problem of localization in cytochemistry is a difficult one, and it is not altogether certain that the basophilic component of the Gram complex normally occurs at the cell wall.

The site of production of pentose nucleotides has an obvious bearing upon the problem of localization of the Gram complex. From their study of both Gram-positive and Gram-negative bacteria, Malmgren and Hedén[3] concluded that bacteria have two nucleotide-forming systems, one of pentose and the other of deoxypentose type, which form a functional unit but are located in separate organelles within the cell.

Our own studies of fusobacteria, clostridia and lactobacilli indicate that the two structures concerned with nucleotide production form a single morphological unit. But regardless of which view is correct, it becomes evident that the presence of pentose nucleoprotein at the bacterial cell wall represents secondary localization. We have attempted to determine whether this secondary localization is the result of a normal physiological process or an artefact produced by the Gram-staining procedure itself.

Young lactobacilli in smear preparations were stained rapidly with dilute basic dye. Large basophilic polar areas were thus revealed, but there were no basophilic areas adjacent to the cytoplasmic membrane as in the Gram reaction. Gram-stained cells decolorized with acid alcohol and restained with dilute basic dye had diffusely distributed basophilia. When the iodine 'mordant' was omitted in this last experiment, the original distribution of basophilia in simply-stained cells was found. It was concluded, therefore, that the iodine solution is responsible for shifting basophilia from the polar areas to the cell wall.

To test this, a series of preparations were stained with Stirling's gentian violet solution, and then placed in an iodine – potassium iodide solution of pH 9·1. Slides were withdrawn at intervals and the Gram staining completed. After 15 min. exposure to the iodine solution, the lactobacilli were Gram-positive, after 30 min. Gram-negative, with Gram-positive polar zones, and after 45 min. again completely Gram-positive. Further treatment failed to effect another reversal of the Gram reaction.

By varying the hydrogen ion concentration, as well as the potassium iodide, it was found possible to influence the speed at which the Gram-negative phase appeared. As the hydrogen ion concentration increased, the time required to reach the Gram-negative phase also increased, while an increase in potassium iodide concentration accelerated the appearance of the Gram-negative phase. It was concluded that there are two basophilic components in lactobacilli which give the Gram reaction; one component is relatively quickly mobilized and can be extracted with iodine solution, whereas the other is only slowly mobilized and cannot be extracted with iodine. Since both basophilic components were hydrolysed by Kunitz-type ribonuclease or $N/1$ hydrochloric acid, it is possible they are pentose nucleoproteins.

The second pentose nucleoprotein component was found as a cortex to nucleal-positive (deoxypentose nucleic acid) polar granules. It differed significantly from the other, since it retained gentian violet staining when the cells were subjected to decolorization without prior iodine treatment.

A less detailed study of *Clostridium septicum* gave results essentially the same as those obtained with lactobacilli.

It is evident that the iodine treatment in the Gram-staining procedure is a complex process involving at least three effects upon various pentose nucleoprotein fractions in the bacterial cell, namely, increased strength of dye binding, alteration of position, and extraction.

The mechanism by which iodine increases dye binding has not yet been elucidated. According to Stearn and Stearn[4], it is due to a greater lowering in the isoelectric point of a protoplasmic component in the Gram-positive organisms than in the Gram-negative. Although no data are on hand to settle the point, a difference in tyrosine content between the pentose nucleoproteins of the Gram-positive and Gram-negative forms could account for such a mechanism, since the iodination of tyrosine increases its acidity[5]. We therefore have reason for suspecting that tyrosine may play an important part in the functioning of cytoplasmic nucleoproteins, and it is of interest to note that Bradfield[6] has postulated that since peptidases do not attack peptides containing phosphotyrosine, it may be possible that combination of tyrosine groups with nucleic acid phosphate might be a means of preventing peptidases from splitting protein during the synthesis of the latter.

This study is from Project No. 323 of the Ohio State University Research Foundation, sponsored by Procter and Gamble of Cincinnati and supervised by Drs. Paul C. Kitchin and Hamilton B. G. Robinson.

Alkaline Phosphatase and Contractile Proteins

ALKALINE phosphomonoesterase is usually defined as an enzyme with a pH optimum around 9·5 which splits monoesters of phosphoric acid. Relatively recently it was found that the comparable acid phosphatase can act as a phosphokinase (Axelrod[1]), and afterwards Meyerhoff[2] showed that alkaline phosphatase also may act as a phosphokinase. The characteristic action of a phosphokinase is the ability to catalyse the transfer of phosphate from one organic molecule to another.

Cytochemical studies have shown that alkaline phosphatase exists characteristically on chromosomes[3], newly formed collagen[4] and at the secretory border of a wide variety of secretory cells[5]. Studies by Rothstein and Meier[6] and Brown[7] have shown that enzymes, including phosphatase, are present even on the external surface of cells. Wilbrandt and Rosenberg[8] have shown that phosphatase is closely associated with the secretory transfer of molecules across cell membranes. Whereas individual theories have been advanced in attempts to explain the association of alkaline phosphatase with individual items of this variety of cytological sites and functions, the explanations as a group have lacked unity. But a unity of pattern emerges immediately if it is assumed that in all cases we are concerned with *contractile proteins*.

It is now well established that the contractility of the protein myosin is closely associated with adenosinetriphosphatase activity. The general theory which is now advanced is that in all the phenomena mentioned in the previous paragraph a not greatly dissimilar contractile protein and phosphatase activity are concerned.

Goldacre[9] has advanced an elegant theory, in which he suggests that amœboid movement and secretion may both be accomplished by contractile proteins. If his theory were correct, contractile proteins would be required at the surfaces of cells, and particularly at those cellular surface sites at which alkaline phosphatase has been discovered by cytochemical methods. It may now be suggested that the function of the alkaline phosphatase at these sites is not simply to hydrolyse phosphate esters, as has hitherto been supposed, but to provide the focal points for release of the energy required for protein contraction and extension. In some cases the whole energy of hydrolysis of a phosphate bond may be required for the process of transfer, so that for each molecule transferred across the cell membrane an orthophosphate ion will appear. But it would be much more economical of energy, and is therefore intrinsically more probable, that for the most part the enzyme acts, not as a phosphatase, but as a phosphokinase, transferring a phosphate group from a high-energy bonding, as in adenosinetriphosphate, to a lower-energy bonding. In such a process the difference in energy between the two bondings would be available for the protein contraction : the transferred phosphate group may appear on the transferred molecule, giving the transfer the overall character of a trans phosphorylation.

Chromosomes are known to contract to a very marked degree in mitosis and meiosis. Phosphatase is commonly present on meiotic and mitotic chromosomes : it is now suggested that the phosphatase represents a key enzymic centre of a contractile protein system which is responsible for the contraction of chromosomes. It is notable that phosphatase is also commonly found in the chromocentres of intermitotic nuclei, which are probably regions of persistent, or perhaps intermittent, chromosome contraction : here also, phosphatase may be an integral part of the contractile protein of the chromosome.

A similar view may be taken of the phosphatase of newly formed collagen. One of the most striking features of the healing of a wound is the contraction which occurs as collagen is laid down. The collagen at the time of contraction is rich in phosphatase, and it is now suggested that collagen is fundamentally a contractile protein and that the phosphatase represents the enzymically active centres concerned either in contraction or in extension. When collagen contraction is complete, there is no further requirement of contractile energy, and it is thus not surprising that mature collagen contains little phosphatase. In vitamin C-deficient guinea pigs, although much protein is formed in healing wounds, it lacks phosphatase, and, as is required by the present theory, no contraction occurs.

Thus all the facts available at the present time are compatible with the view that many of the phosphatases found in animal cells are integral parts of contractile proteins. To separate the enzyme from cells it is often necessary to resort to drastic procedures, including partial autolysis. Thus the soluble phosphatases of the biochemist (for example, kidney phosphatase) often are likely to be, in the strict sense, artefacts.

It is well known that the biological function of a molecule depends upon the nature of the colloids in its environment. Thus when hæm is associated with different proteins, one obtains hæmoglobins of various types, cytochromes, cytochrome oxidases, catalases or peroxidases, according to the natures of the proteins. Further, even with an established type of enzyme activity, the specific degree of activity may vary notably when different supernumerary colloids are in the environment. Keilin and Mann[10] have shown this is the case with carbonic anhydrase, and Keilin and Hartree[11] have observed this phenomenon with succinic dehydrogenase. Consequently, when we consider purified isolated phosphatase, it must be remembered that the protein of the enzyme may well be much modified from that originally present in the cell, and that the remaining enzyme activity may be a very poor guide to the function of the enzyme in the cell. We may even speculate whether the co-existence inside cells of phosphatases and phosphate esters is not made possible by the so-called phosphatases having little or no phosphatase activity when in their correct cellular environment.

With these points in mind, it seems advisable to regard all purified enzymes as at least partial artefacts, until the contrary has been demonstrated.

Histamine Release by Anaphylatoxin

Early studies of the mechanism of anaphylaxis led to two apparently contradictory views : the so-called 'humoral theory', according to which the blood is the site of production of a toxin, the anaphylatoxin[1–4]; and the 'cellular theory', which localizes the anaphylactic reaction in the cells, and assumes that this reaction causes the release of histamine from the tissues[5,6]. The anaphylatoxin theory was based on the finding that guinea pig serum treated with the specific precipitate or with kaolin, barium sulphate, agar, starch or inulin, becomes toxic for the guinea pig and, if injected intravenously, produces symptoms indistinguishable from true anaphylaxis.

The finding by various authors[7,8] that contact of the antigen with washed, perfused lungs of the guinea pig in the absence of blood is sufficient to release histamine led to the general acceptance of the cellular theory and completely obscured the humoral theory. However, in other species, such as the rabbit and the dog, the blood is known to participate in the anaphylactic reaction of histamine liberation[9]. Evidence that the blood, when activated, contains a powerful agent for the release of histamine was first presented by one of us in experiments in which the dog's liver was either perfused with Tyrode solution or with blood. It was known[10,11] that, *in vivo*, enormous quantities of histamine, amounting to milligrams, are released from the dog's liver during anaphylactic and peptone shock. On the other hand, the release of histamine by antigen or peptone from a dog's liver perfused with Tyrode solution amounted to a few micrograms only. If, however, whole blood was used for the perfusion, and particularly if the blood was collected without any anticoagulant in flasks covered with silicone, an entirely different result was obtained. When peptone was added to such blood, which was then pumped through the liver, as much as 8 mgm. of histamine and 25 mgm. of heparine were released[12]. This finding suggested the existence of a powerful histamine-releasing agent in the blood of the dog. A similar discrepancy concerning the release of histamine from the dog's liver was found by Reid[13] with *d*-tubocurarine when it was either injected intravenously or perfused through the isolated liver.

Recently, Hahn[14] has shown that antihistamine substances are able to prevent the shock which is produced in guinea pigs by an anaphylatoxin prepared from a guinea pig serum incubated with inulin. This observation would suggest that anaphylatoxins also act through histamine release, a possibility which was tested and proved to be true by the following experiments.

The lungs of fifteen guinea pigs were perfused with Tyrode solution at a rate of 15–25 ml. per min. After a few minutes perfusion, 4 ml. of 'activated' guinea pig serum was injected into the cannula and the perfusate assayed for histamine on guinea pig's gut. The histamine values were expressed as base. Activation of the serum was by incubation with 0·2 ml./ml. of an agar suspension prepared according to Bordet[3], the so-called agar-anaphylatoxin.

During the first few minutes after the injection of the activated serum, large amounts of histamine were released from the lungs. In one experiment in which the serum had been dialysed before agar treatment, its injection caused the release of 103 μgm. histamine in the course of 10 min.; the maximal output per minute was 23·2 μgm. In other experiments in which activated serum without previous dialysis was injected, the total outputs ranged from 14·3 to 32·6 μgm. (average 23·5 μgm.) and the maximal outputs per minute from 7·3 to 21·3 μgm. (average 14·5 μgm.). These values have to be contrasted with the few micrograms of histamine released by contact of antigen with washed guinea pig's lungs. In such experiments Bartosch, Feldberg and Nagel[7] obtained between 0·5 and 4 μgm., and Daly, Peat and Schild[8] between 0·17 and 12 μgm. of histamine only.

Heating the serum for 30 min. at 60° C. before the addition of the agar suspension abolished, and at 56° C. reduced, the activating effect of the agar. After activation, somewhat higher temperatures were required. Heating activated serum for 1–2 hr. at 60–65° C. diminished its potency in releasing histamine. For example, in four lungs the average output of histamine after the injections of unheated serum was 23·5 μgm. as compared with the average output of 9·5 μgm. from four other lungs following the injection of heated serum. This difference is significant ($t = 4 \cdot 5$; $P < 0 \cdot 02$). After precipitation of the proteins with alcohol at boiling point, or for 15 min. at 65° C., the filtrate, dried *in vacuo* and taken up in 4 ml. water, no longer released histamine from perfused lungs. Dialysis of activated serum did not affect its histamine-releasing property.

The results of these experiments enable us to bridge the two main opposing views concerning the mechanisms underlying anaphylaxis and related phenomena. The presence, in circulating blood, of a powerful histamine-releasing agent which can easily be activated may be of importance not only for anaphylaxis but also for the etiology of a number of other pathological conditions, particularly of allergic phenomena.

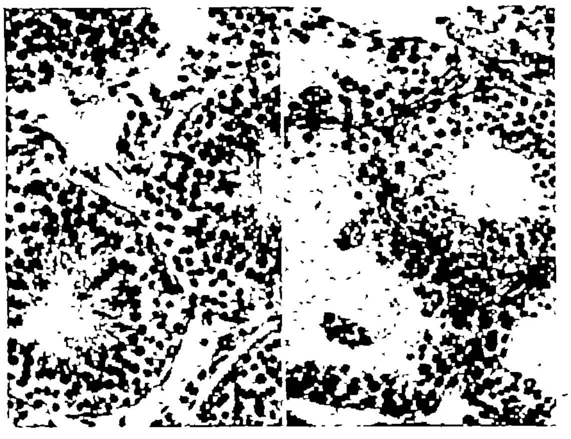
Thyroxine Therapy in Male Infertility

Very little systematic work has been done on the influence of the administration of thyroxine in physiological doses on male infertility in animals of different ages. This seems to have some practical value in the field of reproductive physiology, as male fertility decreases with advancing age and so does the rate of secretion of thyroxine. The question then arises whether any relationship exists between poor fertility and the decline in the rate of secretion of thyroxine in older animals and, if so, what is the effect of the administration of different doses of thyroxine on the male reproductive processes. In the present experiment, nine buck rabbits (inbred strains), which were classed as infertile in view of their poor breeding records, were used for studying the effects of the administration of known doses of thyroxine on libido, semen qualities and testis histology.

Two weeks before the start of the experiment and for eight weeks during the period of treatment with thyroxine, semen samples were collected biweekly by means of an artificial vagina. Sexual desire and semen qualities were estimated for the individual bucks. The results suggested that one of the causes of low fertility in the buck rabbits is a decrease in the rate of secretion of thyroxine which occurs with advancing age, because the administration of moderate doses of thyroxine greatly improved the sexual desire and semen qualities and stimulated the process of spermatogenesis in the seminiferous tubules of the testis of the treated rabbits, which before starting the treatment showed poor sexual desire, deterioration in semen qualities and arrested spermatogenesis (Figs. 1 and 2). A number of giant cells were observed in some of the seminiferous tubules of the testes of the untreated infertile buck rabbits (Fig. 2). The formation of these giant cells appears to be associated with arrested spermatogenesis. A peculiar type of sperm abnormality observed in the semen samples collected from these untreated buck rabbits[1] disappeared with thyroxine treatment, evidently due to the marked stimulation of the process of spermatogenesis, which was observed on histological examination of the testes. The younger buck rabbits responded to the thyroxine treatment comparatively better than the older ones.

The poor sexual desire in the untreated buck rabbits seems to have been due to the interference with the production of the male sex hormone by the interstitial cells of the testes, since on histological examination the interstitial cells showed atrophic changes, with a decrease in number and an increase in the intertubular stroma. I found[2,3] that during the non-breeding season in the young ram there occurs a similar marked decline in libido, semen qualities and in the process of spermatogenesis. Administration of thyroxine in physiological doses to young rams during the non-breeding season practically maintained the sexual desire, semen qualities and the process of spermatogenesis at the same level as that estimated during the breeding season. I have discussed elsewhere[4] the mechanism responsible for the seasonal decline in male fertility. Thyroxine therapy greatly improved the libido and fertility-rate of a young Essex boar, which before treatment showed poor libido and a marked decline in the fertility-rate observed during the summer months.



Sections of the testes of infertile buck rabbits: (1) showing arrested spermatogenesis; the lumina of the tubules contain protoplasmic debris; (2) showing atrophic and degenerative changes, with giant cells in the seminiferous tubules. × 200

The mechanism whereby the thyroid gland influences the male reproductive processes has already been briefly outlined by me[5], and it has been suggested that there is an interrelation between the thyroid, adrenals and gonads[5,6]. Further, addition of thyroxine in critical concentrations to bull semen samples resulted in an increase in the oxygen uptake of the spermatozoa after storage for 24–44 hr. at + 5° C. *in vitro*[7]. The present results show that the administration of thyroxine in physiological doses considerably improves the libido, semen qualities and the process of spermatogenesis in infertile buck rabbits. Detailed results will be published elsewhere.

I would like to thank Dr. J. Hammond and Dr. A. Walton for their help during the course of the present investigation.

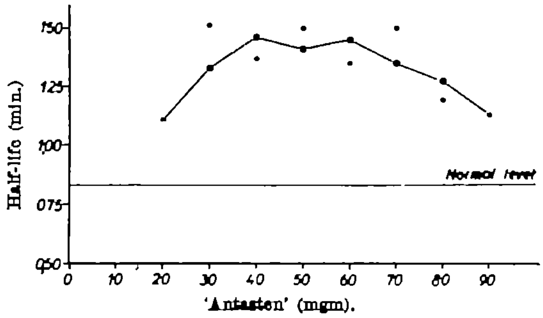
Effect of Antihistamine on the Reticulo-endothelial System; Investigation of Reticulo-endothelial Function with the Aid of Radioactive Chromium Phosphate

IN 1947, Jancsó[1] put forward the view that histamine is an activator of the reticulo-endothelial system and antihistamine is an inhibitor. Halpern and his co-workers[2] carried out investigations on the subject which supported Jancsó's observations. Biozzi[3] has reported that antihistamines prevented the absorption of indian ink by endothelial cells.

In the investigations here, the influence of antihistamine on the colloid-absorbing ability of the reticulo-epithelial system was examined by means of intravenous injection of a radioactive chromium phosphate suspension (labelled with phosphorus-32),



Biological half-life in the blood of intravenously injected labelled chromium phosphate in rats after subcutaneous treatment with different doses of 'Antasten'. ○, Mean of individual observations (10 animals in each group). ●, Moving mean values

Method. The antihistamine used was 'Antasten' (Ciba, Switzerland: 2-phenylbenzylaminomethyl-imidazol). The colloid-absorbing ability of the reticulo-endothelial system was estimated in two ways:

(*a*) By determining the biological half-life of intravenously injected radioactive chromium phosphate in the blood of animals treated with 'Antasten' and comparison with normal values. This shows the rate at which the reticulo-endothelial system removes the colloid from the blood circulation.

(*b*) By investigating the effect of 'Antasten' treatment on the distribution in the body of the intravenously injected radioactive chromium phosphate[4,5].

All experiments were carried out on white laboratory rats of a body-weight of 140–150 gm. and of both sexes. Eighty rats were injected with different doses of 'Antasten', as was done by Jancsó. Ten rats in each group were injected with 20, 30, 40, 50, 60, 70, 80 and 90 mgm. in two equal portions at 30-min. intervals. Fifteen minutes after the last injection, the reticulo-endothelial system functional test was carried out, and the biological half-life of the radioactive chromium phosphate in the blood was determined.

In the second series, thirty rats were used. Five groups of five animals were treated with different doses of 'Antasten', 20, 40, 60 and 80 mgm., in the same way as in the first series; as a control, five rats were injected with an isotonic saline solution instead of 'Antasten'. Fifteen minutes later, all the animals were injected with the chromium phosphate preparation, and two hours later they were killed and the radioactivity of the different organs was determined.

Table 1. BIOLOGICAL HALF-LIFE OF RADIOACTIVE CHROMIUM PHOSPHATE IN THE BLOOD AFTER SUBCUTANEOUS INJECTION OF VARIOUS DOSES OF 'ANTASTEN' (COMPARED WITH CONTROLS WITHOUT 'ANTASTEN' INJECTION)

Dose of 'Antasten' in mgm.	Biological half-life (min.)	
	Exp. animals (10 per group)	Control animals (25)
20	1·11 ± 0·05 0·147	
30	1·51 ± 0·15 0·460	
40	1·37 ± 0·07 0·218	
50	1·50 ± 0·07 0·224	0·83 ± 0·05 0·250
60	1·35 ± 0·11 0·334	
70	1·50 ± 0·09 0·293	
80	1·19 ± 0·08 0·266	
90	1·13 ± 0·09 0·271	

$\bar{X} \pm s\bar{X}$ = mean of individual observations and its standard error

σ = standard deviation of observations

Results and Discussion. Table 1 and the accompanying graph show the collected results of the biological half-life determinations in the series of eighty rats. The radioactive colloid circulates longer in the blood after treatment with 'Antasten' than it does in normal animals, and the uptake of the colloid in the reticulo-endothelial system is retarded. The biological half-life is distinctly prolonged after 20 mgm. of 'Antasten' and still further prolonged with 30 mgm. There is no further increase with doses between 30–70 mgm., and with doses of 80 and 90 mgm. the biological half-life approaches the normal value. Table 2 shows the statistical analysis of the results obtained.

Table 2. DIFFERENCE IN BIOLOGICAL HALF-LIFE AFTER VARIOUS DOSES OF 'ANTASTEN' (CF. TABLE 1 AND GRAPH). ANALYSIS OF VARIANCE

Type of variance	Sums of squares	d.f.	Variance	*F*	*P*
Between class	2·03	7	0·29	3·41	$0·01 < P < 0·001$
Within class	6·08	72	0·08		
Total	8·11	79			

The analysis of variance (Table 2) shows that the variation between the half-life values in the graph could not have arisen at random. Furthermore, the component mean values which constitute the curve differ significantly from the control values, as is obvious on mere inspection of the values in Table 1 and the graph.

In a previous report[5], it was shown that the ratio of distribution of radioactive colloids was constant in normal animals for the liver, spleen and lungs. The control animals injected with an isotonic saline solution exhibited similar amounts of radioactivity in the liver, spleen and lungs as those treated with various doses of 'Antasten'. These experiments have shown that 'Antasten' does not have any particular point of attack in the reticulo-endothelial system.

The results above indicate that 'Antasten' has a significantly inhibitory effect on the rate of colloid absorption in the reticulo-endothelial system; but with the methods employed it was not possible to show any special inhibition of the reticulo-endothelial cells of the liver, spleen or lungs.

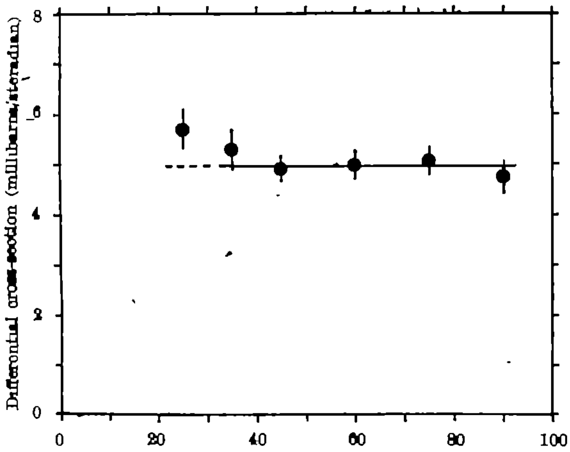
Proton–Proton Scattering at 146 MeV.

A PROTON beam has been extracted from the 110-in. Harwell cyclotron by scattering the internal beam at a uranium target[1]. Deflected protons escape from the cyclotron along a path sheltered from the magnetic field by an arrangement of iron bars[2]; but sufficient field remains to separate outgoing protons of different energies. Protons of 147 ± 1 MeV., as determined by their corrected[3] range in aluminium, are selected by slits and passed down an evacuated tube 12·7 metres long to a point behind a concrete screening wall. A flux of 2×10^6 protons-cm.$^{-2}$-sec.$^{-1}$ is available at the end of the tube, and this is monitored by an ionization chamber and an integrating D.C. amplifier.

The external beam has been used first for a study of proton–proton scattering with the results shown in the accompanying graph. The experiment has been carried out with polyethylene scatterers, the effect of the carbon present being subtracted with the help of graphite scatterers.

Relative cross-sections between 35° and 90° were measured by coincidence counting of both the protons involved in each collision. At 35° a very thin scatterer had to be used because the energy of one of the protons is much reduced at small angles of scattering. At 25° only the 'forward' proton could be detected, and the results at this one angle may



Differential cross-section for proton–proton scattering as a function of centre of mass angle. The incident protons had a laboratory energy of 146 ± 1 MeV. The errors shown are statistical standard deviations on the relative measurements at the various angles. The absolute cross-section at 90° has been found to be 4·99 ± 0·31 millibarns-steradian^{-1}, and the weighted mean of the points between 35° and 90° has been normalized to this value

have been affected by systematic errors. When only one proton was being counted the carbon effect increased greatly, so that the final result was obtained from a small difference between two much larger counting-rates. The errors given in the graph are the statistical standard deviations on these relative measurements.

The absolute cross-section was obtained through a comparison of the differential proton–proton cross-section at 90° with the cross-section for the $^{12}C(p,pn)^{11}C$ reaction. This reaction was observed by irradiating a clear naphthalene crystal and afterwards examining it with an *E.M.I.* photomultiplier, guard crystals being used to prevent any of the carbon-11 decay positrons from escaping. The efficiency of detection of these positrons during the calibration run was found to be 87·2 ± 1·7 per cent by fitting an integrated Fermi distribution to the bias curve of counting-rate against discriminator voltage. This value for the efficiency was checked by the usual coincidence method, using a sodium iodide crystal to detect annihilation γ-rays. The ratio of the differential proton–proton cross-section at 90° to the $^{12}C(p,pn)^{11}C$ cross-section was found to be 0·0787 ± 0·0031 at an effective energy of 146 ± 1 MeV., allowance being made for the slowing down of the primary protons in the scatterer and crystal. The stated standard deviation is intended to cover likely systematic errors. Adopting[4] 63·4 ± 3·0 millibarns for the $^{12}C(p,pn)^{11}C$ cross-section, the differential proton–proton cross-section at 90° was calculated to be 4·99 ± 0·31 millibarns-steradian^{-1}. Since the relative cross-sections between 35° and 90° showed no evidence of anisotropy, the angular distribution measurements were normalized so that the weighted mean of these five points was equal to 4·99 millibarns-steradian^{-1}.

Proton–proton scattering at high energies has previously[5–7] been found to be isotropic at 100, 240 and 345 MeV. The absolute magnitude of the cross-section given here is also quite consistent with these three sets of results, but it is rather higher than that found by Chamberlain, Segrè and Wiegand[8] in another series of experiments, in which the external proton beam of the Berkeley cyclotron was slowed down by absorbers. In terms of the theory of Jastrow[9], the higher cross-section suggests that the proposed central repulsion in the proton–proton interaction is at a radius not greater than 0·50 × 10^{-13} cm.

Much of the apparatus used in this experiment was made by Mr. R. A. Gibbons and assembled by Messrs. P. H. Bowen and L. Bird. The proton monitor was supplied by Mr. L. Pittendrigh. The work was greatly assisted by the enthusiastic co-operation of Mr. A. O. Edmunds and the cyclotron crew.

Radiocrystallographic Study and Molecular Weight of Actinomycin from *Streptomyces* S-67

THE crystals of actinomycin obtained by one of us[1] are prismatic monoclinic needles, with the length parallel to the binary axis. The mean values of the angles between the most frequent faces are:

$p(001)$	:	$h^1(100)$	00° 17′
$h^1(100)$		$a^1(10\bar{1})$	71° 20′
$p(001)$	·	$a^1(\bar{1}01)$	39° 23′
$e^1(011)$	:	$g^1(010)$	63° 35′
$m(110)$	:	$g^1(010)$	53° 27′

The ratios of the parameters obtained from these values are:

$$a : b : c = 0{\cdot}793 : 1 : 0{\cdot}531$$

and the angle β is 110° 43′.

The crystals are optically positive. A thin plate (001) shows an optic axis pole at the limit of the field. The plane of the optic axes is parallel to $g^1(010)$ and the greatest refractive index n_γ is in the direction nearly perpendicular to $p(001)$ in the obtuse angle of the b- and c-axes. No dichroism was observed.

Rotating crystal radiograms were taken with a, b, c and [101] as rotating axes. The pictures generally show diffraction spots only in the proximity of the direct beam.

The spots corresponding to the b- and [101]-axes are sharp and the length of the axes deduced from these radiograms are:

$$b = 27{\cdot}30\ kX. \quad (101) = 21{\cdot}72\ kX.$$

The radiogram corresponding to the c-axis is not very well defined; apparently, however, there is a periodicity which together with that of the b-axis gives the value $c/b = 0{\cdot}524$, in agreement with the goniometric results.

From the very accurate value of the b-axis, and using the goniometric ratios, the length of the a-

and *c*-axes may be calculated with an accuracy which we think is better than that obtained by the absolute measure of the axes. So we have

$$a = 21\cdot 64\ k\text{X.}; \quad c = 14\cdot 50\ k\text{X.}$$

The volume of the unit cell, $V = abc \sin \beta$, is 8,012 $k\text{X.}^3 \pm 1$ per cent.

The density, measured accurately with the Berman torsion balance, is $1\cdot 18 \pm 1/2$ per cent.

From the well-known formula

$$n = \frac{V.d}{M \times 1\cdot 65},$$

we have *nM* (molecular weight of the unit cell) = 5,730.

The number of molecules in the unit cell is unknown.

We determined the proline in actinomycin hydrolysate by microbiological assay[2] and calculated the molecular weight on this basis. 100 mgm. of actinomycin were hydrolysed by refluxing for 48 hr. with 6 *N* hydrochloric acid at 110°. The residue was evaporated to dryness, a small quantity of water was added and the suspension was filtered. The volume of the filtrate was made up to 100 c.c. by washing the filter. For the microbiological assay, 15 c.c. of the resulting solution was diluted to 100 c.c., to give a solution containing 150 γ of actinomycin per c.c.; 24·3 γ per c.c. of proline was found. The probable accuracy of this result appears to be ± 5 per cent, judging from simultaneous assay of a known mixture of amino-acids.

From the molecular weight of proline (115), it is possible to calculate the molecular weight of actinomycin:

$$\frac{150 \times 115}{24\cdot 3} = 710 \pm 35$$

(assuming one mole of proline per mole of actinomycin).

On the basis of the above calculations, the number of molecules per unit cell appears to be eight, and the molecular weight of actinomycin would be 716 ± 15.

The Rast cryoscopic method, however, gives a lower value (576)[1], and in this case the calculated molecular weight may be 573 (assuming that there are ten molecules per unit cell).

The value obtained from the microbiological assay appears to be better than the one obtained by cryoscopy, because of the very low solubility of the actinomycin in camphor.

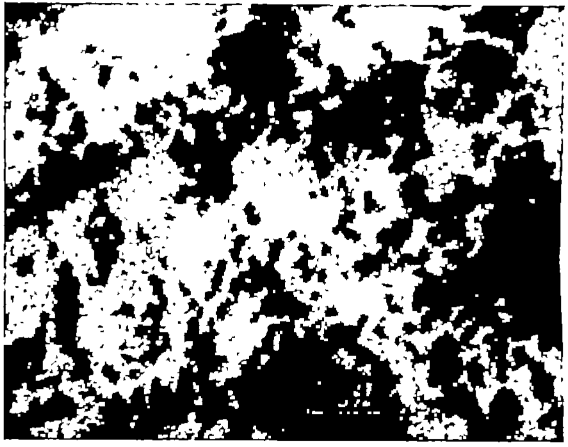
An Electron Microscope Study of Nucleic Acid

Probably the only macromolecules which have been observed directly are some of the larger proteins seen with the electron microscope. Although many polymers have a molecular size as great as these proteins, the width of the polymer chains is too small for them to be visible. The following observations on nucleic acid, however, suggest that these molecules can be seen individually.



A preliminary study has been made in the electron microscope of calf thymus sodium nucleate prepared by Signer, Butler and Fraser. In general, micrographs were obtained of replicas of the surfaces of dried drops from aqueous solution or smeared sheets of thymonucleate, the replicas being prepared by shadowing the thymonucleate with palladium – gold at $\tan^{-1} 1/6$ and coating with a 'Formvar' film. The replica was then floated off on the surface of water or a dilute solution of sodium hydroxide, when the thymonucleate dissolved. Other methods of preparation were also used; but that described is superior in avoiding shadowing of structure due to the 'Formvar' itself. The specimens before replicating were all faintly birefringent.

All the specimens examined showed globules of varying diameter with an average value of about 100 A. This would be compatible with a polymer having a distribution of molecular weights about a mean value of approximately 10^6. Close examination of the clear regions of the micrographs (see accompanying reproduction) suggests that they are genuinely free of globules; that is, the thymonucleate molecules are in a form the details of which are below the resolving power of the electron microscope. A spurious effect, due possibly to diffraction or shadowing, was seen on a few micrographs which could be interpreted as showing the molecules as fibres of about 50 A. diameter, in support of Oster and Nixon's observations[1]; but otherwise no evidence has yet been obtained of any fibrillar structure, although occasionally globules tend to align themselves to give the appearance of a fibre similar to those found by Scott[2]; it is not certain, however, to what extent this effect is due to drying.

A tentative explanation of these results is that, on drying, surface molecules are unstable and coil up; but in the bulk of the material the molecules remain extended owing to the intermolecular forces and lie parallel to one another, as shown by X-ray diffraction, birefringence, etc. (see, for example, ref. 3). The breadth of a polynucleotide chain is expected to be about 15–20 A., so that in the extended state the molecules are below the resolution of the microscope. Occasionally, therefore, the 'smooth' formation of the bulk material is seen in regions free from coiled molecules.

Further work is in progress, and a more detailed account will be published later.

I wish to thank Prof. R. Signer, Dr. J. A. V. Butler and Dr. M. J. Fraser for sodium thymonucleate; Prof. J. T. Randall for advice and encouragement throughout the work; and Dr. M. H. F. Wilkins for the preparation of some of the specimens and for valuable discussions.

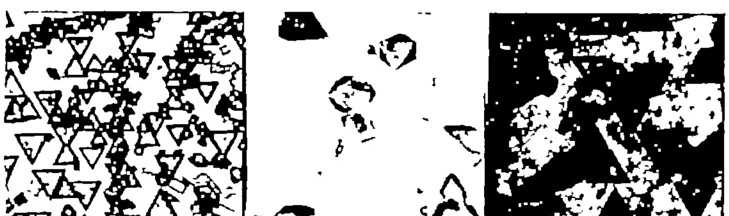
Epitaxis of Rubidium Iodide on a Barium Stearate Substrate Deposited on Mica

The oriented overgrowth formed by rubidium iodide on a mica substrate has been recorded by Royer[1] and others. In the course of repeating these experiments the substrate was modified; instead of a muscovite substrate, barium stearate deposited on freshly cleaved muscovite was used, the deposit being built up as a succession of monomolecular layers.

Rubidium iodide crystallizing from an aqueous solution on a substrate of glass or of barium stearate (one to nine molecular layers) on glass does so in the cubic habit, whereas on mica the crystal outline is in most cases an equilateral triangle with sides parallel to the traces of the (010), (110) and ($1\bar{1}0$) planes of mica, the (111) plane of rubidium iodide being parallel to the (001) plane of mica. Some crystals, however, assume the cubic habit in random orientation with respect to the mica; but if dilute solutions are used their number is very much reduced. If the crystallization is carried out on barium stearate layers deposited on the mica, the proportion of unoriented cubic crystals increases with the thickness of the barium stearate barrier.

Layers of one, three, five, six, seven and nine monolayers were used, and with nine layers oriented crystals only occasionally appeared. It appeared, therefore, that a barium stearate barrier of nine molecules thick was sufficient to eliminate the influence of the mica.

In the (111) plane of rubidium iodide, the directions of greatest atom density are those which form the boundaries of the triangular crystals. The directions next to these in atom density would outline a hexagon; hexagonal crystals, which are absent when rubidium iodide crystallized directly on mica, appeared when a barrier of barium stearate of three, five or seven layers was interposed; also the triangular crystals frequently grew in connected groups of three, especially when deposition was on a monomolecular barrier.



(1) Rubidium iodide crystals grown on mica. (2) Rubidium iodide crystals grown on a three-molecule layer of barium stearate deposited on mica, showing the development of hexagonal outlines (*a*), an unoriented cubic crystal (*b*), and a connected group of three (*c*). (3) Connected groups of three crystals growing on a monolayer of barium stearate on mica. In each photograph the longest side is parallel to the *b*-axis of the mica, and the magnification × 60

The layers of barium stearate were deposited by dipping a freshly cleaved mica slip, c. 50 mm. × 7·5 mm., through a monomolecular layer of barium stearate spread on a water surface, the technique being that described by Blodgett[2].

I wish to acknowledge the assistance of Mr. D. C. Bisset of this Department, who undertook the deposition of the monolayers.

Intense Gallium X-Rays for Microradiography and Diffraction Investigations

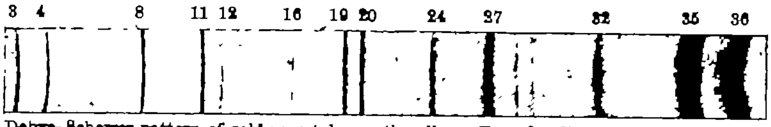
The identification of segregates in ferrous and non-ferrous alloys by the technique of microradiography[1-4] is now established as an extremely valuable complement to the conventional optical micrographic procedures. The contrast between segregate and matrix is independent of the etching characteristics of the metal, but depends, instead, on the relative absorption of the X-ray beam through a finite depth of specimen. Since the linear absorption coefficient μ is $C \, . \, N^4\rho\lambda^3$, where N is the atomic number of the absorbing element, ρ its density, λ the wave-length of X-rays and C a constant between absorption edges, it follows that, provided suitable wave-lengths are available, a segregated element may be positively identified by X-ray methods alone. When it is sought to distinguish between two elements close to each other in atomic number, it is possible to accentuate the contrast in X-ray absorption by choosing a radiation with a wave-length lying between the K-absorption edges of the elements.

For the bulk of alloys normally investigated, the range of wave-lengths available for microradiographic examination is, on the whole, quite adequate, with the exception of the commercially important group which comprises the brasses. As shown in the accompanying table, the only radiation capable of discriminating satisfactorily between copper and zinc-rich segregates is the $K\alpha$-radiation of gallium, and this radiation has hitherto not been available.

On account of its extremely low melting point (29·75° C.), it would be impossible to employ gallium as a target material in the normal types of sealed-off or demountable X-ray tubes, unless the current were kept down to a few micro-amperes. This in its turn, would make exposure periods inordinately long and quite impracticable except for very special purposes. However, the situation is quite different when a rotating anode X-ray tube is employed. By carefully

Target material and wave-length in A.		Linear absorption coefficient μ Cu	Zn
0·559	Ag	236	201
0·585	Pd	265	233
0·613	Rh	303	269
0·708	Mo	448	391
1·339	Ga	3440	426
1·433	Zn	425	350
1·538	Cu	470	421
1·656	Ni	580	514
1·786	Co	720	620
1·933	Fe	882	780
2·100	Mn	1080	970
2·287	Cr	1370	1206

cleaning the cylindrical copper surface of the 4-in. diameter anode of a 'Gyrotron' X-ray tube[5], it was quite a simple matter to cover its slightly warmed surface with a uniform thin layer of gallium, simply by rubbing it on until it adhered. A continuous output of X-rays corresponding to a mean current of 80 m.amp. at 40 kVp. with focal spot dimensions 0·8 mm. × 8·0 mm. could easily be achieved. During the emission of X-rays, the gallium at the focal spot is, of course, liquid, but instantly freezes on moving away from the electron stream. So adherent is the film and so short is the period in which it is liquid, that no gallium is thrown off the anode surface due to centrifugal forces, nor, because of the efficient cooling, is there any intergranular attack which would cause disintegration of the copper base.



Debye–Scherrer pattern of gold wire taken with gallium $K\alpha + \beta$-radiation in 9-cm. diameter camera. Exposure 60 m.amp., 40 kVp., 1¼ min.

Since the focal spot is small, the intense beam of gallium radiation may also be employed for X-ray diffraction work. A typical Debye–Scherrer diffraction pattern of gold wire in the 'as drawn' condition and taken in a 9-cm. diameter camera with gallium $K\alpha + \beta$-radiation is reproduced herewith. The exposure period, with the tube operating at only 60 m.amp. and 40 kVp., was approximately 1¼ min.

The wave-length of gallium $K\alpha$-radiation is appreciably shorter than that of copper $K\alpha$. Thus, in suitable cases, much more information may be obtained from gallium radiation diffraction patterns than copper, since additional reflexions at higher values of $\sin\theta/\lambda$ are possible.

The availability of this new radiation emphasizes the advantages of a rotating anode X-ray tube over the conventional demountable tube fitted with a stationary target. Not only does it make more power available with normal radiations, thereby curtailing exposure times, but also its flexibility enables entirely new techniques to become available.

I should like to express my thanks to the Mond Nickel Co., Ltd., for permission to publish this communication.

Applications of Multiple-Beam Interferometry

PROF. S. TOLANSKY[1] has made some comments on communications by Bruce[2] and Bruce, Macinante and Kelly[3] on the production and applications of transmission-like reflexion fringes. I am grateful for the reference to the paper by Lummer[4] in which the principle of eliminating beams in a Haidinger fringe system is mentioned.

The first of our communications refers to a Fizeau fringe system, where the relevant beams were eliminated practically, in a very simple manner. The transmission-like reflexion fringes so produced were used with particular success in vibration measurement. No claim is made for the extensive use of such fringes in the topographical study of small areas where high magnification is required. They have been produced in the low-magnification systems so frequently used in the interferometry of length.

It is not suggested that the reflexion fringes shown in the communication are the optimum in contrast, and it is agreed that reflexion fringes may be used in vibration studies; but we have found the transmission-like reflexion fringes a distinct advantage in our work.

The second communication, on vibration measurement, had been submitted for publication before we had seen the papers by Tolansky[5] and Tolansky and Bardsley[6].

Sonic Layers in the Sea

THE article on 'scattering' layers in the sea by A. C. Burd and A. J. Lee in *Nature* of April 21[1] was read by us with much interest since such layers have been frequently observed in Scottish waters during the past three years.

The increasing use of the echometer as a fish-locating device during the past few years has raised the important problem of the assignment of characteristic echo traces to specific sound-reflecting surfaces. Hodgson[2] has shown that it may be possible at certain seasons and at particular times of the day to distinguish between shoals of several species of fish by the shape, density and texture of the echo traces; but traces are often obtained which cannot so readily be ascribed to particular organisms. Among these is the type, illustrated by Burd and Lee, which appears as a diffuse layer with the lower boundary frequently ill-defined; it is often recorded for long distances as an uninterrupted trace at varying depths from the sea-bed. For example, in our records such traces have extended for distances up to 35 miles on the

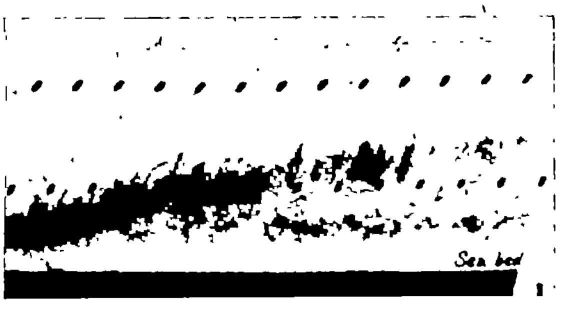

Fig. 1. Specimen of diffuse scattering layer obtained on M/S 12 Kelvin Hughes 14 kc./s. echo-sounder aboard the Scottish Home Department's F.R.S. *Clupea* while operating on Peterhead fishing grounds, August 5, 1948. (Depth marks on echo-trace are at 0, 20, 40 fathoms, etc., and the time interval between marks is 3 min.)

Moray Firth herring grounds. Some of our traces show the vertical migration observed by Burd and Lee, whereas others have been observed in the upper water layers in full daylight. This suggests that the 'scattering' layers may be produced by a variety of pelagic forms which sometimes are associated in the same layer. An interesting example in support of this is shown by the trace in Fig. 1 (supplied by Dr. H. Wood). This was detected near the sea-bed at sunset on August 5, 1948, on the Peterhead fishing grounds. On the approach of darkness the trace split into two parts, one of which rose towards the surface and stopped in the neighbourhood of a sharp thermocline, while the other persisted at a level about 10 fathoms from the sea-bed.

In order to ascertain the nature of this type of trace, we attempted to photograph the organisms with an underwater ciné-camera and a 1,000-watt light source, and to observe their reaction to underwater light stimuli. During 1950 some identifiable photographs (including fish and jellyfish) were obtained. One experiment in particular revealed something of the reactions and the type of the organisms producing traces of this nature. On July 20, 1950, off Fraserburgh, an extensive sonic layer was picked up in darkness at 0100 hr. This trace appeared as a diffuse record at approximately six fathoms from the surface. The vessel was stopped, and the sequence of events was as follows (the results being illustrated in Fig. 2). (1) The lamp was lowered a few feet below the surface of the water, and was switched on and left in this position for 15 min.; the scattering layer descended to a depth of approximately 10 fathoms and gradually increased in density. (2) The lamp was switched off for 3 min.; the layer remained dense and rose rapidly towards its previous level. (3) The lamp was lowered into the middle of the layer and was switched on; the greater part of the trace descended immediately to 20 fathoms; but some organisms remained at the level of the light. (4) The light was hauled to the surface and held there for 10 min. The main part of the scattering layer rose quickly to 10 fathoms; but some organisms rose to the surface. (5) The light was then switched off and the main body of the trace rose to its original level of approximately 6 fathoms.

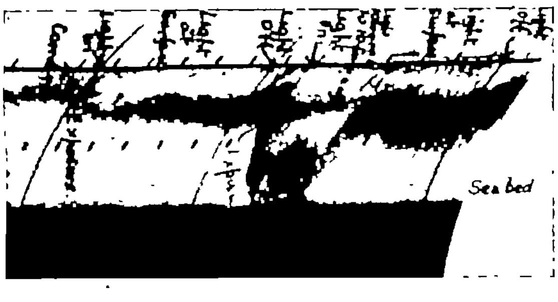

Fig. 2. Echo-trace illustrating experiments referred to in text. Time sequence of events indicated by numbered arrows. (Each tick denotes the passage of 3 min.)

The conclusions which we draw from these observations are: (*a*) Most of the organisms giving rise to this scattering layer were very active swimmers; their descent from 10 to 20 fathoms in a few seconds presumably eliminates from sole consideration such drifting forms as medusæ and the smaller plankton organisms. (*b*) The main body of the trace resulted from organisms showing positive phototaxis to a light intensity corresponding to that at a depth of 10 fathoms below the 1,000-watt lamp. (*c*) A smaller portion of the trace was composed of organisms showing a greater positive phototaxis, being attracted to within a few feet of the lamp; these we were able to identify from samples taken with a small hand-scoop as young scaled three-bearded rockling (*Onos tricirratus*) of 4–8 cm. in length, and sand eels (*Ammodytes spp.*) of 10–15 cm. in length, in the ratio of approximately 20 : 1.

In the absence of identifiable photographs on this occasion, it is not possible to determine to what extent these two species contributed to the main body of the patch which concentrated at approximately 10 fathoms below the light source, and in view of the difference in reaction to the light stimuli it is probable that species other than these fish were also present. Presumably a similar specific difference holds for Fig. 1.

These observations seem to have general interest in relation to the conflicting beliefs held as to the nature of the *deep* 'scattering' layers—whether they are of physical or biological origin. Testing their reactions to lights in their neighbourhood might help to resolve this question with high probability.

The presence of fish as one component of this type of scattering layer provides a possible explanation of our failure to secure more identifiable photographs with the camera-light unit used in these experiments. This particular unit had independent switches for the light and camera, the camera being set in operation before the light. Fig. 2 demonstrates clearly the immediate flight response of part of the scattering layer to light stimuli, which would have taken the organisms responsible rapidly out of the field of focus of the camera. Some species of fish are also known to adopt similar flight reactions to sound stimuli, and it is possible, therefore, that the noise made by the ciné-camera mechanism would have caused a similar flight response. During the present season a single-frame camera with electronic flash is being used. In this way it is hoped that all component organisms will be photographed before any movement away from the field of focus of the camera can be effected.

Further records of the presence of diffuse scattering layers in Scottish waters have come to our notice from a number of herring fishermen. One such record, kindly provided by Skipper G. Leslie of the drifter *Betty Leslie*, and from the Shetland herring grounds in June 1950, is of interest in providing further evidence of the presence of young fish in the scattering layer. In this instance a widespread diffuse trace, similar to those illustrated above, was obtained from the upper water layers, and Skipper Leslie shot his drift-nets at the trace depth. Although the trace persisted during the whole of the time that the nets were in the water, the total catch was only one adult herring; but entangled in the nets were vast numbers of small fish, a sample of which was collected and identified as post-larval unscaled herring of 3–4 cm. in length.

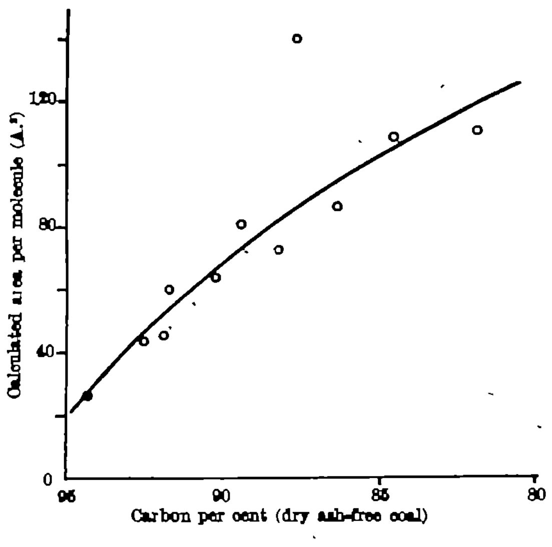
Adsorption on Coal

IN a recent letter in *Nature*[1], Lecky *et al.* have reported that surface areas of coal obtained from low-temperature nitrogen adsorption are considerably smaller than areas determined from water and methanol adsorption, while Malherbe[2] found a similar discrepancy between areas of coal determined from low-temperature argon adsorption and heats of wetting in methanol. The doubts thus cast on the extent of the internal surface area of dry coal samples do not, however, necessarily apply to coal in its wet and swollen state, and it is in this form that coal is encountered in wet processing and also, as dust, in the lungs of coal-miners.

I have studied adsorption of organic molecules from aqueous and alcoholic solutions on coal. Adsorption on high-rank coals (for example, the anthracites) is often very high, even with low molecular weight solutes which give no evidence of multimolecular adsorption, suggesting that for these coals the heat of wetting in methanol does not over-estimate the internal surface. The area per molecule of solute, calculated from the apparent adsorption at final concentrations of 0·100 *N*, decreases as the rank of coal (and percentage carbon) decreases and the oxygen content increases. The accompanying graph gives results for the area per solute molecule in the case of acetic acid, heats of wetting in methanol being used as a measure of specific surface[3].

A similar gradation in the calculated areas is found with other solute molecules in aqueous solution, for example, formic acid, methyl and ethyl alcohol, methyl and ethyl acetate. The slope of the curves is dependent on the particular solute, being least pronounced for methyl alcohol. Adsorption presumably takes place through the non-polar portion of the solute molecule; Traube's law for homologous series is valid for coal except in cases where molecular sieve action is pronounced.



The gradation in calculated area per molecule is probably largely due to a true decrease in adsorption per unit area as the coal becomes more hydrophilic. Dependence of heats of wetting on the composition of the surface may be a contributory factor.

The available results will be more fully reported elsewhere. The observations reported above were obtained on coal samples supplied by the British Coal Utilization Research Association, by whom the heat of wetting determinations were carried out.

Observation of Cool Flames with Ethylene

IN the course of investigations into the inflammability of ethylene/oxygen/nitrogen mixtures, some interesting observations have been made on the type of flame produced by spontaneous ignition at 300°. Experiments were carried out in a cylindrical steel bomb (explosion cavity 3·8 cm. dia. and 15·3 cm. long) mounted vertically and fitted with a quartz window near the top.

Several mixtures, containing 5–6 per cent of oxygen and 15–68 per cent of ethylene, were fed into the bomb at 300° and pressures up to 40 atm., and found to give rise spontaneously to two quite different types of flame.

(1) At 17–41 atm., a pale blue flame moving downward through the mixture. The flame front was about ⅛ in. thick, nearly planar, and possessed no tail. It travelled at a speed of approximately 1 cm./sec. and was associated with a gentle pressure 'pulse' of 0·5–1·0 atm. Titanic sulphate indicated small quantities of peroxides in samples of the gas taken immediately before or immediately after the passing of the flame. 50–90 per cent of the oxygen was consumed, 20–28 per cent being converted to formaldehyde and 1–2 per cent to acetaldehyde.

(2) At 25–41 atm., normal ignition occurred. The flame was bright red and moved too rapidly for visual perception of the flame front, that is, at least at (and possibly much faster than) 50 cm./sec. Much soot was produced and the gauge registered a sudden kick that sometimes exceeded 30 atm. No peroxides were detected, but all the oxygen was used up, about 16 per cent being converted to formaldehyde and 1–2 per cent to acetaldehyde.

The pressure at which the flame characteristics changed depended on the composition of the gas, and for each gas was located within a range of some 2–3 atm. Within this range, a two-stage ignition could sometimes be observed, the blue flame being followed by a normal ignition in the space of about one second.

The low-pressure flame has the following characteristics of a 'cool' flame: (i) pale blue and non-luminous; (ii) slow speed; (iii) small pressure pulse; (iv) capacity to lead to a two-stage ignition; (v) associated with peroxide and aldehyde formation.

Up to the present, however, attempts to produce similar flames artificially in cold gas mixtures with a feebly glowing platinum spiral have not met with any success.

Townend, in a study of the auto-ignition of ethylene/air mixtures[1], found no evidence of cool flames despite exploration over a wide range of values of temperature, pressure and composition. Since the present study differs only from this work in composition, namely, a greater quantity of nitrogen for all ethylene concentrations, it seems likely that the diluent effect of the nitrogen is a vital factor in the formation of cool flames in ethylene.

These observations were made in the Fuel Department of the University of Leeds, and we wish to express our appreciation of the interest taken by Prof. A. L. Roberts in this work. A detailed account will be published in due course. We wish to thank the directors of the British Oxygen Company, Ltd., for permission to publish this letter.

Mode of Decomposition of Sulphur Sesquioxide

Wöhler and Wegwitz[1] tentatively assumed the formation of sulphur monoxide as an unstable intermediate compound in the decomposition of sulphur sesquioxide and thus accounted for the formation of thiosulphate and polythionates. Neither Partington and Vogel[2] nor Wöhler and Wegwitz obtained sulphur monoxide during the decomposition.

While studying the properties of sulphur sesquioxide, I heated a sample of the sesquioxide in an all-glass apparatus at 60° C. The volatile products of decomposition, when cooled in a U-tube immersed in liquid air, condensed to a pale yellow solid. On shaking with cold dilute alkali, this yellow residue gave rise to sulphide, sulphite, thiosulphate and sulphur.

When sulphur monoxide prepared by the combustion of sulphur in oxygen at low pressure (Schenk[3]) is cooled at the temperature of liquid air, a similar yellow condensate is obtained. On hydrolysis with cold dilute alkali the condensate gives rise to sulphide, sulphite, thiosulphate and sulphur, as in the case of the products of decomposition of sulphur sesquioxide mentioned above. It is thus concluded that the condensates in the two cases are the same. In other words, this experiment shows that the sulphur monoxide is produced during the decomposition of sulphur sesquioxide. It may be mentioned that the formation of the products of alkali hydrolysis has been explained by B. S. Rao[4] on the basis that disulphur monoxide is produced during the decomposition of sulphur monoxide.

Further support for this observation comes from the following experiment. When sulphur trioxide is led into a solution of sulphur in dry carbon tetrachloride, a dark blue solution of the sesquioxide is obtained. On subjecting this to alkali hydrolysis, it is noticed that sulphide, sulphite, thiosulphate and sulphur are produced. No detectable amounts of polythionates are formed. The production of sulphide during the hydrolysis of sulphur sesquioxide has been observed for the first time, and this is attributed to the production of sulphur monoxide as the primary product during the hydrolysis. The results of a representative experiment are:

Amount of sulphur (mgm.) in carbon tetrachloride (80 gm.)	Sulphur (mgm.) as SO_3 added to carbon tetrachloride	Products of alkali hydrolysis (in mgm.)			
		Sulphur as sulphide	Sulphur as sulphite	Sulphur as thiosulphate	Free sulphur
97·92	97·92	18·2	99·2	36·8	40·9

It is presumed that sulphur sesquioxide can decompose in two ways:

$$\text{(i)}\quad S_2O_3 \longrightarrow S + SO_3$$
$$\text{(ii)}\quad S_2O_3 \longrightarrow SO_2 + SO.$$

The amount of sulphur monoxide produced can be calculated quantitatively from the products of alkali hydrolysis by the method developed by B. S. Rao[4]. It has been found in this case that 82 per cent of the decomposition of sesquioxide goes according to reaction (ii). This value is in good agreement with the percentage (80 per cent) obtained by the German authors. It can therefore be concluded that sulphur monoxide is one of the primary products of decomposition of sulphur sesquioxide.

Further details of the work will be published elsewhere.

I wish to express my thanks to Dr. B. Sanjiva Rao and Dr. M. R. Aswathanarayana Rao for their interest in this work.

Paper Chromatography of Nicotinic Acid Derivatives

Leifer *et al.*[1] have reported the paper chromatography of nicotinic acid with the use of microbiological assay. While our work was in progress, Huebner[2] described a spot test for detection of some pyridine derivatives. The present work describes sensitive qualitative techniques developed in this Laboratory for the detection of tertiary and quaternary pyridinium compounds. The laborious procedure involved in the microbiological method of Leifer *et al.*[1] is obviated by rapid colour or fluorescent tests. For the colour test, advantage was taken of König's[3] reaction, namely, the formation of coloured compounds when tertiary pyridine derivatives are treated with cyanogen bromide and a primary aromatic amine. The fluorescence test allows the detection of quaternary nicotinamide derivatives. Use is made of the formation of bluish-white fluorescent substances when quaternary pyridine compounds with a side chain CO—NH—*R* in the β position are treated with methyl ethyl ketone and ammonia[4].

From a number of solvent systems, those were chosen which allowed the best separations of the various compounds (Tables 1 and 2). After descending chromatograms had been run on Whatman paper No. 1 overnight, the papers were dried at room temperature and treated in the following way.

(1) *Tertiary pyridine compounds.* The dry paper was placed in a closed glass tank for 1 hr. at room temperature over a cyanogen bromide solution, prepared according to Wang and Kodicek[5]. It was then sprayed with 2 per cent *p*-aminobenzoic acid (2 gm. of *p*-aminobenzoic acid dissolved in 75 ml. 0·75 *N* hydrochloric acid and made up to 100 ml. with 96 per cent ethanol). The positions of the different compounds are revealed by their colours (see diagram). It is possible to detect quantities as small as 0·1 microgram.

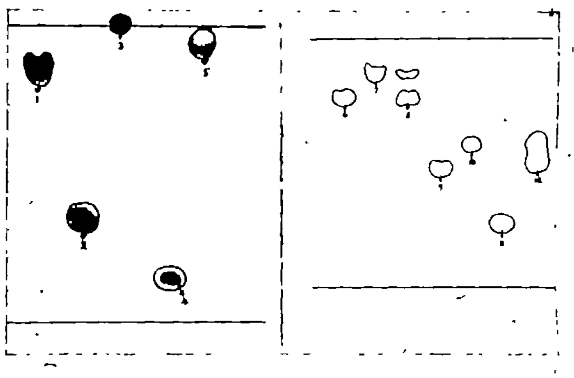
(2) *Quaternary pyridinium compounds.* The dry paper was placed over a mixture of methyl ethyl ketone and ammonia (1 : 1) for 1 hr. in a closed glass tank at room temperature. The relative positions could be detected by their bluish-white fluorescence under ultra-violet (see diagram). Quantities as small as 0·05 μgm. (nicotinic acid equivalents) could be detected.

Table 1. R_F VALUES OF SOME TERTIARY PYRIDINE COMPOUNDS (DESCENDING CHROMATOGRAMS)

Material	Solvent System					Colour
	n-Butanol, water	*n*-Butanol. water + 0·1 per cent ammonia (bottom)	*iso*-Butanol, water	80 per cent acetone	Methyl ethyl ketone . acetic acid : water, 49 · 1 · 50 .	
Nicotinic acid	0·21	0·19	0·17	0·55	0·68	yellow
Nicotinamide	0·69	0·69	0·69	0·78	0·59	deep yellow
Nicotinuric acid	0·11	0·06	0·08	0·44	0·45	orange
Diethyl nicotinamide (coramine)	0·90	0·89	0·91	0·89	0·90	pink

The R_F values of some nicotinic acid derivatives determined by these techniques are listed in Tables 1 and 2. The R_F values of the leading front were taken.

The results show that the R_F values of nicotinamide and coramine were more or less consistent irrespective of the solvent used, whereas those of the more acidic compounds (nicotinic acid, nicotinuric acid) moved slower in neutral or alkaline than in acidic solvents.



(*a*) *n*-butanol – water (*b*) 60 per cent *n*-propanol

Descending chromatograms in (*a*) *n*-butanol, water and (*b*) 60 per cent *n*-propanol

(*a*) Coloured spots from tertiary nicotinyl compounds treated with cyanogen bromide and *p*-aminobenzoic acid (1) nicotinic acid; (2) nicotinamide; (3) bound nicotinic acid preparation; (4) diethylnicotinamide (coramine); (5) nicotinuric acid. (*b*) Fluorescent spots from quaternary nicotinamide compounds treated with methyl ethyl ketone and ammonia (6) diphosphopyridine nucleotide; (7) triphosphopyridine nucleotide; (8) mixture of (6) and (7), (9) N′-methylnicotinamide; (10) N′-methylnicotinuric acid betaine; (11) 3-carbamyl-*tetra*-acetyl-N′-D-glucosidyl pyridinium bromide; (12) 3-carbamyl-N′-2′-hydroxyethyl pyridinium bromide

Thus, for example, the R_F value for nicotinic acid was 0·70 when *n*-butanol–water–1 per cent acetic acid was used, compared to 0·21 in *n*-butanol–water.

The bound nicotinic acid (a purified preparation from wheat bran[6]) did not move with any of the solvents investigated, indicating, in agreement with the findings of Chaudhuri and Kodicek[6], that the nicotinic acid is bound to a moiety which makes it insoluble in the organic solvents tested (see diagram).

The butanol, 80 per cent acetone and methyl ethyl ketone solvent systems were most suitable for the tertiary nicotinyl series. For the quaternary nicotinamide derivatives, with the exception of the diphospho- and triphospho-pyridine nucleotides, 60 or 80 per cent propanol proved to be the most suitable solvents. For diphosphopyridine nucleotide and triphosphopyridine nucleotide, 60 per cent acetone, 60 per cent *n*-propanol or 60 per cent ammonium sulphate in *M*/10 phosphate buffer (*p*H 6·8) with 2 per cent *n*-propanol were the best solvents.

When diphosphopyridine nucleotide was developed in the 60 per cent ammonium sulphate system, two spots were observed with R_F values of 0·38 and 0·86, respectively. The second spot, which is only faintly fluorescent, is most probably due to a split product formed by the action of the solvent system. Its R_F value is identical with that of the quaternary nicotinyl riboside, kindly supplied by Dr. L. J. Haynes.

Table 2. R_F VALUES OF SOME QUATERNARY PYRIDINIUM COMPOUNDS (DESCENDING CHROMATOGRAMS)

Material	Solvent system				Method of detection
	60 per cent acetone	80 per cent acetone	60 per cent *n*-propanol	60 per cent ammon. sulphate in phosphate buffer (*p*H 6·8) with 2 per cent *n*-propanol	
N′-methylnicotinamide	0·71	0·47	0·64	0·83	Bluish-white fluorescence
N′-methylnicotinuric acid betaine	0·57	0·26	0·43	—	,,
Carbamyl-N′-2′-hydroxyethyl pyridinium bromide*	0·74	0·36	0·57	—	,,
Diphosphopyridine nucleotide	0·43	0·10	0·26	0·38	,,
Triphosphopyridine nucleotide	0·30	0	0·15	0·54	,,
3-Carbamyl-*tetra*-acetyl-N′-D-glucosidyl pyridinium bromide*	0·94	0·84	0·81	—	,,
3-Carbamyl-N′-ribosidyl pyridinium bromide*	0·62	0·33	0·48	0·86	,,

* Prepared by Haynes and Todd (ref. 7).

N′-Methylnicotinuric acid betaine could not be traced in the ammonium sulphate solvent system. This may be due to the removal of glycine with ammonium sulphate from the β side-chain, thus leaving a carboxylic group which would not give a fluorescent condensation compound with methyl ethyl ketone and ammonia[4].

Further work is in progress to apply these procedures to biological materials.

We wish to thank Dr. L. J. Haynes for supplying us with some of the quaternary nicotinyl compounds and Dr. E. C. Slater for the gift of diphosphopyridine nucleotide and triphosphopyridine nucleotide.

New Lateral Line Sensory Organs in *Xenopus lævis* Daudin

During an investigation of a trematode infestation in *Xenopus lævis* a median ventral row of 'lateral' sensory organs was observed, which has not previously been described[1]. The observation was due to the nature of the infestation, and Fig. 1 is a photograph of a parasitized adult female toad. The parasites (*Strigeid metacercariæ*) encyst in all layers of the dermis beneath the lateral sense organs, and the position of these is emphasized by numerous large melanophores close to the cysts, while the rest of the skin remains paler than usual.

The median ventral row runs forward from the junction of the two ventral rows just anterior to the anus, and consists of three to six 'plaques'. It is an anterior continuation of the row that joins the anus to the lateral ventral rows, which Paterson[2] suggests are derived from the paired rows on the ventral fin of the tadpole. The median ventral row can sometimes be seen in normal animals, but is very inconspicuous. Its presence in these has been confirmed histologically (Fig. 2).

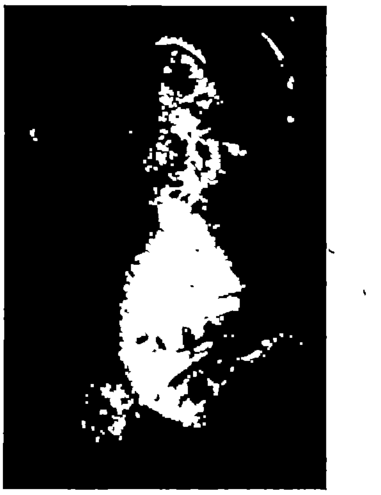

Fig. 1. *Xenopus lævis* D. Adult female with metacercarial infestation of the lateral line system. The melanosis provoked by the parasites discloses the presence of a hitherto unsuspected median ventral line

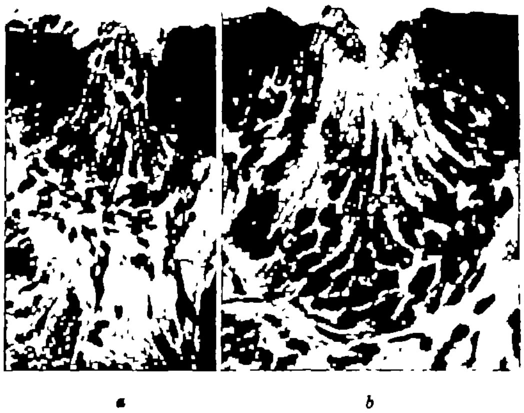

Fig. 2. (*a*) Sensory epidermal bud from the median ventral 'lateral' line of *Xenopus lævis* D. Some nerve fibres, supplying the organ, are visible. × 180. Holmes silver impregnation. (*b*) Sensory epidermal bud from the upper lateral line of *Xenopus lævis*. × 270. Masson's trichrome. Note the presence of the central depression on the surface which is absent in (*a*)

The median ventral row differs from the other rows in that the plaques are short (less than 2 mm.) and are not raised above the surrounding skin; tactile organs, which usually alternate with the lateral line neuromasts along the plaque, are often absent, and the latter are smaller than usual, scarcely extending down into the dermis. The innervation appears normal.

Fuller accounts of these observations, of the infestation and of an investigation into the electrophysiology of the lateral sensory organs of *Xenopus* by one of us (R. W. M.), will be published elsewhere.

The So-called Chromosome-Races of *Cardamine pratensis* and *Nasturtium officinale*

In his recent article on "Plant Chromosome-Races and their Ecology in Great Britain"[1], Dr. G. Haskell devotes a paragraph each to lady's smock (*Cardamine pratensis*) and to watercress (*Nasturtium officinale* agg.). So far as *Cardamine pratensis* is concerned, he omits to mention the work of Hussein[2,3], who has made by far the largest study of the distribution of the two chromosome-races of this plant in Great Britain. Haskell states that in Great Britain, as in Sweden, the form with the lower chromosome number ($2n = 30$) is characteristic of drier conditions than the form with the higher chromosome number ($2n = 56$). This was found by Hussein, who says: "The ecological difference found by Lövkvist holds good in most of the cases recorded; for example, Prof. R. D'O. Good, who kindly provided material from Dorset, noted particularly that the large plant, now found to have the low chromosome number, occurred in quantity on the damp roadside banks characteristic of Marshwood Vale, whereas the smaller darker-leaved one ($2n = 56$) grew in wet meadows". It should also be noted that the chromosome number of *Cardamine pratensis* from Merton was found by Lawrence[4] to be $2n = 30$ (thus agreeing with counts made by Lövkvist[5] and Hussein[2,3] and with unpublished counts by myself for the lower chromosome number form) and not $2n = 32$ as stated by Haskell, although Lawrence did suggest that it may have arisen from $2n = 32$ by chromosome fusion.

Watercress should surely not have been included as an example of chromosome-races since, although Manton[6] suggested that the forms with $2n = 32$, 48 and 64 were diploid, triploid and tetraploid races of the same species, later work by Howard and Manton[7,8] showed conclusively that there are two quite distinct species of watercress, *Nasturtium officinale sensu stricto* with a chromosome number of $2n = 32$ and *N. microphyllum* (or *N. uniseriatum* as Howard and Manton called it) with $2n = 64$. The form with $2n = 48$ is the interspecific hybrid *N. microphyllum* × *officinale*. Moreover, it was shown quite conclusively that *N. microphyllum* was an allotetraploid and therefore that any differences between it and *N. officinale* were most likely to be due not to polyploidy but to the influence of other, unfortunately still unknown, parent species of *N. microphyllum*. Further, as Airy Shaw[9] has pointed out, the tetraploid species of watercress, namely, *N. microphyllum*, had been distinguished for many years by several European botanists as a distinct species.

It should also be noted that diploid watercress, namely *N. officinale sensu stricto*, is a perennial and not an annual as Haskell states and that Haskell's description of *N. microphyllum* as perennial winter watercress is misleading in another respect. The brown or so-called winter cress of the commercial grower is the hybrid *N. microphyllum* × *officinale* and not *N. microphyllum*, which is not cultivated[10]. Also, green or so called summer cress, *N. officinale*, is cultivated for winter use at the present time on a very large scale and the terms 'winter' and 'summer' cress are therefore to a large extent misnomers. It may be, as Haskell suggests, that *N. officinale* occurs in areas with a higher mean rainfall and *N. microphyllum* in areas with a lower mean rainfall; but when we mapped our records[11] for the distribution of the two species, it was not apparent to either Mr. A. G. Lyon or me. The suggested distribution is, moreover, an exception to the general rule proposed by Haskell in his last paragraph that tetraploids, not diploids, occur in the wetter places; but, if correct, it is easily understandable when we remember, as has been pointed out earlier, that *N. microphyllum* is an allotetraploid and not an autotetraploid. There is, however, further evidence about the distribution of the two watercress species which Haskell has omitted. Both Airy Shaw[12] and Howard and Lyon[11] give reasons for suggesting that *N. microphyllum* can tolerate lower *p*H values and calcium concentrations than *N. officinale*. It is hoped that further observations on this point will be published soon in *Biological Flora* accounts for the two species. Lastly, in discussing the distribution of watercress, it must always be remembered that, in addition to being a wild plant, watercress is cultivated in the south of England and that for many centuries prior to its cultivation it was eaten as a salad plant by man.

[12] Airy Shaw, H. K., Rep. Bot. Soc. Brit. Isl. Conference of 1948, p. 75.

I am indebted to Dr. H. W. Howard for criticisms and comments on my survey of the ecology of British chromosome-races[1]. The following points may also be added.

(1) I am pleased to learn of Miss Hussein's studies on the distribution of *Cardamine pratensis* in Britain. However, in her map[2] she did not relate the widespread distribution of the higher chromosome-race and the restricted southerly distribution of the lower race to colonization following retreat of the ice.

(2) Lawrence[3] gave $2n = 30$ for the Merton *C. pratensis* and interpreted this as reduction from 32 through chromosome fusion. I put $2n = 32$ to avoid confusion with genuine aneuploidy due to actual loss of chromosomes.

(3) Dr. Howard's criticism of my using the term 'chromosome-race' with regard to *Nasturtium* species and their hybrid is of much wider significance. Darlington[4] has pertinently asked recently whether the chromosomes fit the species, and the problem of polyploid races within and between species has now been discussed at length by Löve[5]. He believes that all chromosome-races should be recognized as distinct species (even if morphological differences are slight), except asexually reproducing higher, uneven hybrids. Löve maintains that all chromosome-races show morphological differences when carefully examined and uses the term 'polyplotype' to refer to a polyploid regardless of whether it is an auto- or allo-polyploid. This is useful, as Stebbins[6] has already indicated that many so-called auto-polyploids could be interpreted as allo-polyploids.

(4) Manton[7] referred to the summer watercress crop as being diploid and the winter crop as triploid. She said there was a marked tendency for diploids to behave as annuals unless conditions were especially favourable in the autumn, and ease of perennation was in part at least responsible for the use of the higher polyploid in winter. Dr. Howard's more recent observations will therefore clarify this point.

FORTHCOMING EVENTS

Wednesday, September 19

Institute of Petroleum (at Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Dr. Morris Muskat: "Our Unproduced Reserves—What are They ?"

Friday, September 21

Television Society, Engineering Group (at C.E.A., 164 Shaftesbury Avenue, London, W.C.2), at 7 p.m.—Mr. H. Page: "Slot Aerials".

Saturday, September 22

Biochemical Society (at the Rowett Research Institute, Bucksburn, Aberdeenshire), at 11 a.m.—Scientific Papers.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Analyst (with associateship of the R.I.C and, preferably, experience in the analysis of foods and drugs) in the Department of the Public Analyst—The Registrar and Secretary, The University, Bristol (September 22).

Assistant Lecturer (Grade III) and a **Lecturer** (Grade II) **in the Department of Botany**—The Secretary, The University, Edmund Street, Birmingham 3 (September 22).

Senior Lecturer in Advanced Non-Ferrous Metallurgy to Honours B.Sc. (metallurgy) standard—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (September 22).

Director of the City Art Gallery and Museum—The Town Clerk, Town Hall, Wakefield (September 24).

Scientific Technologist (with a good general training in chemistry, preferably up to degree standard) in the Coal Survey Laboratory at Leeds—The National Coal Board, Establishments (Personnel). Hobart House, Grosvenor Place, London, S.W.1, quoting TT/368 (September 24).

Biochemist (non-medical) **in the Pathological Department**—The Secretary, Nottingham No. 1 Hospital Management Committee, General Hospital, Nottingham (September 29)

Lecturer in Chemistry—The Principal, Norwood Technical College, West Norwood, London, S.E.27 (September 29).

Lecturer to teach Metallurgy to engineering students preparing for the London University degree in engineering, and other examinations—The Clerk to the Governors, Woolwich Polytechnic, Woolwich, London, S.E.18 (September 29).

Lecturer in Experimental Pharmacology—The Secretary of University Court, The University, Glasgow (September 29).

Lecturer or an **Assistant Lecturer in the Zoology Department**, University College, Ibadan—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 29).

Assistant Plant Pathologist (with an honours degree in botany, and with special training in mycology)—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh (September 30).

Educational Psychologist (with Bachelor of Education degree or honours degree in Psychology)—The Secretary, Scottish Education Department, 14 Queen Street, Edinburgh 2 (September 30).

Lecturer (with a first- or second-class honours degree in mechanical engineering) **in the Department of Applied Mechanics**—The Director of Studies, Royal Naval College, Greenwich, London, S.E.10 (September 30).

Professor of Anatomy—The Registrar, University College of South Wales, Cathays Park, Cardiff (September 30).

Chemists (Experimental Officer grade) at a Ministry of Supply research establishment in Berkshire. (Ref. F.626/51A) with experience of gas analysis (Ref. F.627/51A) experienced in factory development work; (Ref F.628/51A) inorganic or physical chemist with knowledge of analytical procedure—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (October 8).

Engineers I at a Ministry of Supply establishment in London: (Ref. C.509/51A) to be responsible for production, conversion and repair of aircraft, turbine engines and accessories, planning programmes and progressing, (Ref. C.510/51A) to be responsible for planning and progressing of specialized sub-contract supplies, vetting proposals for capital expenditure, and statistical analysis; (Ref. C.511/51A) to be responsible for planning and progressing the supply of engine accessories, including magnetos and ignition systems, also gun-turrets and tool kits—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (October 8).

Principal Scientific Officer (with a first- or second-class honours degree in a science subject or in mathematics, or an equivalent qualification and, preferably, experience of fundamental research in chemistry) at the Norfolk Flax Establishment, King's Lynn—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4072/51 (October 11)

Lecturer in Zoology at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 13).

Physics Graduate for a research appointment in Microwave Spectroscopy—The Secretary, University College, Southampton (October 15)

Scientific Assistant (with a university degree in electrical or mechanical engineering or physics) **in the Department of Science and Industry**—The Director, City Museum and Art Gallery, Birmingham 3 (October 15).

Examiners (male, with a University degree in either physics or chemistry; some postgraduate research experience an advantage) **in the Gas Standards Branch**, Ministry of Fuel and Power—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4073/51 (October 18).

Forest Entomologist at the Forest Research Station, Alice Holt, Farnham, Surrey—The Secretary, Civil Service Commission, 6 Burlington Gardens, London, W.1, quoting 4071/51 (October 18).

Lecturer in the Department of Botany (with special qualifications to lecture (through the medium of the Afrikaans language), guide and conduct research in cytogenetics, or systematic botany of lower plants)—The Registrar, University of Pretoria, Pretoria, South Africa (October 30).

Research Assistant (with at least two years research experience and, preferably, a Ph.D.) **in the Department of Chemistry**, to carry out experimental work on Friedel-Crafts polymerization and related problems—Dr. P. H. Plesch, Chemistry Department, University College of North Staffordshire, Keele, Staffs (October 30).

Research Plant Biochemist—The Head, Plant Physiological Institute, University of Pretoria, Pretoria, South Africa (October 30).

Director (with a scientific training, preferably in zoology or anthropology) **of the Otago Museum**, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Senior Lecturer in Inorganic Chemistry at the University of Melbourne—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Holbrook Gaskell Chair of Botany—The Registrar, The University, Liverpool (November 17).

Engineer and **Ship Surveyors** and **Nautical Surveyors** in the Marine Survey Service of the Ministry of Transport—The Principal Establishment and Organization Officer, Ministry of Transport, Room 6029, Berkeley Square House, London, W.1 (December 1).

Agricultural Economist (with a degree in agriculture, horticulture or economics, and experience of investigational work), and an **Assistant Agricultural Economist** (with a degree in agriculture, horticulture or economics)—The Registrar, Wye College, Wye, Ashford, Kent.

Assistant Chief Engineer (Development) by the Division of Atomic Energy (Production), Capenhurst, Chester, to take charge of a development team engaged on the construction and operation of prototype plants, involving both mechanical and chemical engineering—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

Assistant Chief Engineers (Design), to take charge of teams of engineers and draughtsmen engaged on the design and detailing of special mechanical and chemical plant for manufacture on a production basis, and **Engineers** (Design), to undertake the duties of project engineers, including the design of special plant and equipment and the layout required for efficient manufacturing processes—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, stating post applied for.

Chemist III at a Ministry of Supply establishment at Chislehurst, to be responsible for metallurgical analysis section and deputy to the Officer-in-Charge of laboratories—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.634/51A.

Chemists (Experimental Officer grade) at Ministry of Supply research and development establishments mainly in the vicinity of Waltham Abbey, Sevenoaks, South-East London and Staffordshire—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.607/51A.

Chemists (2, honours degree in chemistry essential, and textile experience an advantage) for research on problems relating to the dyeing and finishing of knitted products—The Secretary, Hosiery and Allied Trades Research Association, Thorneywood House, 4 First Avenue, Sherwood Rise, Nottingham.

Circuit Engineer (with experience of radar pulse techniques) for work on digital electronic computing machines—The Secretary, British Rayon Research Association, Barton Dock Road, Urmston, Manchester.

Development Engineers by the Division of Atomic Energy (Production), Capenhurst, Chester, to assist in the construction and operation of prototype plants, involving mechanical and chemical engineering—The Ministry of Supply, Division of Atomic Energy (Production). Risley, Warrington, Lancs.

Electrical Engineer to design electrical equipment, including H. T. and L. T. switchgear, substations, and internal installations for large chemical factories, and an **Instrument Engineer** to undertake the design, provision and maintenance of instruments for the measurement of radioactivity and for the control and recording of pressures, temperatures and the flow of liquids and gases in pipes—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, stating post applied for.

Electrical Engineers and **Physicists** at a Ministry of Supply research and development establishment near London: (Ref. D.390/51A) **Electrical Engineers** (Senior Scientific Officer grade) with special qualifications in radio communications and experience in the engineering of development prototypes, (Ref. A.245/51A) **Physicist** (Senior Scientific Officer grade) with experience in electronic circuitry for research into the measurement of high speed transients; (Ref. A.246/51A) **Physicist** (Senior Scientific Officer grade) with experience of optical and electronic techniques, and with an interest in fluid mechanics, for work on aerodynamics problems including wind tunnel investigations; (Ref. D.392/51A) **Electrical Engineer** or **Physicist** (Scientific Officer grade) with interest in the application of electronic methods to optical instrumentation techniques; (Ref. D.391/51A) **Electrical Engineer** or **Physicist** (Scientific Officer grade) for work on high speed electronic calculating machine—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Engineers and **Physicists** (Experimental Officer grade) at the Royal Aircraft Establishment, Farnborough, and an out-station in Bucks: (Ref. D.396/51A) capable of development of electronic techniques and equipment, and special experience of miniaturization, or V.H.F. and U.H.F. radio and radar techniques an advantage; (Ref. D.397/51A) with experience in light mechanical and electrical mechanisms and equipment, and capable of research and development work in electronics, aircraft instrumentation, servo mechanisms, or analogue computing and automatic pilots—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

EXECUTIVE ENGINEER IN THE PUBLIC WORKS DEPARTMENT, Nigeria—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27322/4.

GRADUATE (with a knowledge of chemistry or physics up to a degree standard, and a good knowledge of French and/or German) IN THE LIBRARY AND INFORMATION DEPARTMENT—The Director of Research, British Leather Manufacturers' Research Association, Milton Park, Egham, Surrey.

HEAD OF THE DEPARTMENT OF RADIO AND MUSICAL INSTRUMENT TECHNOLOGY—The Clerk, Northern Polytechnic, Holloway, London, N.7.

HYDROBIOLOGIST in the Sudan Government Fisheries Section, to work on freshwater hydrobiological problems in the Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Hydrobiologist 4/312'.

JUNIOR ASSISTANT PHYSICIST—The Secretary, Royal Infirmary, Bradford.

LECTURER IN GEOLOGY—The Registrar, The University, Nottingham.

LECTURER IN MATHEMATICS—The Clerk to the Governing Body, Battersea Polytechnic, Battersea, London, S.W.11.

MECHANICAL AND ELECTRICAL ENGINEERS (New Construction) for service in the Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Mechanical and Electrical Engineer, 4/320'.

METALLURGIST (with a good university degree in metallurgy and a sound knowledge of physical chemistry) for a new important research in connexion with electrical sheet steel—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1.

PHYSICAL CHEMISTS (Scientific Officer grade) at Ministry of Supply experimental establishments mainly in the vicinity of Waltham Abbey, Sevenoaks and South-East London, for research and development work in the field of physical chemistry—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.603/51A.

PHYSICIST or PHYSICAL CHEMIST (with a good honours degree and preferably an interest in the physical properties of materials) for work on fundamental problems associated with the hardening of Portland Cement—The Cement and Concrete Association, 52 Grosvenor Gardens, London, S.W.1.

PROFESSIONAL CIVIL ENGINEERS at the London office of the Crown Agents, in conjunction with the location, design and construction of a major bridge in East Africa—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.27777.A.

RESEARCH ASSISTANT (with a science degree and preferably some postgraduate research experience in chemistry) to take part in a programme of research in physical chemistry (reaction kinetics)—The Registrar, University College, Exeter.

RESEARCH and DEVELOPMENT CHEMISTS and PHYSICISTS by the Division of Atomic Energy (Production), Capenhurst, Chester, to take charge of small teams of technical staff engaged on research and development work for a new factory—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, stating post applied for.

RESEARCH OFFICER (Forest Chemist) IN THE FORESTRY DEPARTMENT, Federation of Malaya—The Director of Recruitment (Colonial Service), Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27106/45.

SCIENCE OR ENGINEERING GRADUATES to do research on either the flow of fluids through porous substances, or the theory of atomization of liquids—The Registrar, Imperial College of Science and Technology, South Kensington, London, S.W.7.

SCIENTIFIC ASSISTANT (Analyst) for the East African Agriculture and Forestry Research Organization—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.27761.G.

SENIOR ELECTRICAL AND MECHANICAL ENGINEER for service in the Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Senior Electrical and Mechanical Engineer, 4/320'.

SENIOR LECTURER (with high academic or professional qualifications, qualified to teach a main branch of chemistry to honours degree, and to direct research) IN CHEMISTRY—The Principal, Royal Technical College, Salford 5.

SENIOR LECTURER IN MATHEMATICS (to teach pure and applied mathematics up to general degree standard, and certain sections up to honours standard)—The Clerk, Northern Polytechnic, Holloway, London, N.7.

SENIOR LECTURER IN PHYSICS—The Principal, Sir John Cass College, Jewry Street, London, E.C.3.

SENIOR LECTURER IN RAYON TECHNOLOGY at Bradford Technical College—The Director of Education, Town Hall, Bradford.

SENIOR LECTURER, and an ASSISTANT LECTURER, IN PHARMACEUTICAL CHEMISTRY—The Secretary, Royal Technical College, Glasgow.

SENIOR SCIENTIST, a BOTANIST, an AGRONOMIST, and a SOIL SCIENTIST, in the Research Division of the Sudan Ministry of Agriculture, for work at a new station for agricultural research on rain grown crops—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Senior Scientist 4/316a', 'Botanist 4/316b', 'Agronomist 4/316c', or 'Soil Scientist 4/316d', as applicable.

SOIL SURVEY OFFICER in the Department of Soil and Land-Use Survey, Gold Coast—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27059/162.

TUTOR (with an honours degree in science or mathematics, with physics as primary interest) in Berks, Bucks and Oxon—The Secretary, Services Education Committee, 7 Wellington Square, Oxford.

WOOL TEXTILE RESEARCH COUNCIL SCHOLARSHIPS for research on (a) woollen yarn manufacture, (b) cloth finishing, (c) for an investigation of the quantitative absorption of mordants—The Principal, Technical College, Queen Street South, Huddersfield.

GOVERNMENT RESPONSIBILITY IN CIVILIAN SCIENTIFIC RESEARCH

IN January 1947, the Advisory Council on Scientific Policy was appointed "to advise the Lord President of the Council in the exercise of his responsibility for the formulation and execution of Government scientific policy". Its appointment has been amply justified, for not merely in the field of scientific man-power but also over the whole range of national economy it has become increasingly important to have a permanent means for ensuring that the scientific resources of Great Britain are effectively utilized in the national interest. The rearmament programme and the demands on scientific man-power and resources likely to result from the implementation of the Colombo Plan and other schemes for the economic development of backward territories in various parts of the world emphasize further the need for an overall survey, in order to ensure that resources are wisely distributed, and also to keep in balance the civil and defence aspects of research policy, as is done by the appointment of a common chairman for the Advisory Council on Scientific Policy and the Defence Research Policy Committee.

Already the work of the Advisory Council during the past four years has shown that opportunities exist for it to watch over and improve the arrangements for securing an adequate supply of scientific workers to meet the needs of the Government and industry, including the provision of adequate facilities for their training, and for the dissemination of information resulting from scientific research; and it is encouraging to note from the fourth annual report surveyed elsewhere in this issue (p. 491) that the Advisory Council appears to have overcome the diffidence with which it approached the man-power situation a year ago, for it has appointed, after consultation with the Ministry of Labour and National Service and the University Grants Committee, a standing Committee on Scientific Man-power. However, apart from special questions, such as those arising out of the use of potentially toxic substances in consumer goods, where the Advisory Council can assist in formulating a common and agreed interdepartmental policy, it is clear from the present report alone that there are other problems in which all the authority and prestige of the Council will be continuously required to avoid distortion of the country's scientific and technical effort and of the use of its resources in directions that may seriously hinder the meeting of other and more important commitments.

This is pointed out by the Advisory Council specifically in regard to demands which may be made upon our resources of scientific man-power in connexion with projects under the Colombo Plan or like schemes. It makes a similar reference in commenting on a report from the Committee on Atomic Energy. The proportion of scientific resources which is now being devoted to atomic energy and nuclear physics in general is a matter of considerable concern, and may well be out of balance. This particular question is one of priorities, and possibly cannot be resolved even by the Advisory Council on Scientific Policy without some reference to the Defence Research Policy Committee. That may equally apply to some other aspects of national expenditure on civilian research and development which the Advisory Council has at present under review, bearing in mind the restriction on the use of man-power and resources caused by the diversion, in the present economic situation, of so much of the nation's effort to re-armament. The Advisory Council is considering, in particular, the scientific responsibilities which the Government has rightly assumed, and the extent to which government expenditure on civilian research could safely be restricted.

That review is not complete; but in the meantime scientific workers and industrialists will welcome one point made in the present report. Government organizations, like other research institutions, cannot be built up quickly in a stable and effective form. The Advisory Council is convinced that experienced research teams should be kept together in civilian establishments, and that urgent defence work should be assigned to them, rather than that attempts should be made to transfer individuals to defence establishments; in this view the Defence Research Policy Committee and the defence departments have concurred.

Whether or not the review now proceeding foreshadows a considerable curtailment of the research and other scientific services which government establishments are able to offer to industry, the rising costs of equipment, materials and labour are likely to have that effect, even if the establishments of the Department of Scientific and Industrial Research are not diverted to defence work to any considerable extent. Any appreciable increase in the appropriation for civilian research and development must be regarded as unlikely, although the Advisory Council considers it important to maintain a normal rate of recruitment in scientific establishments. Such recruitment will compete with what may be an increasing demand from industry, at least on its rearmament side; but there is no suggestion in this report of what the demand may be from the defence establishments.

These circumstances give special interest to the recently issued memorandum on "Government Scientific Organization in the Civilian Field"*, which embodies the results of a survey which has been conducted by the Council during the past six months. This memorandum traces the growth over the past fifty years, describes the existing organization in Great Britain, and shows the government expenditure on scientific research in the civilian field from 1900 to 1950, together with summarized estimates for 1950–51. While the role of the universities in fundamental research is indicated, no account is taken of appropriations to the universities in the estimate of some sixteen million pounds for government expenditure on scientific research in the civilian field for 1950–51, nor is any attempt made to assess what proportion of the government grants of £11,000,000 for recurrent and £4,000,000 for capital expenditure to the universities in this period could be regarded as for scientific purposes.

The figure cited in this memorandum must therefore be regarded as a minimum, and not as representing the full expenditure by the central Government on scientific work in the civilian field. Nor is account taken of some expenditure by the Ministry of Supply and the Admiralty on scientific research which is preponderantly in the field of defence, but which has a significant application to the needs of civil industry. That by the Ministry of Supply covers the work on atomic energy at Harwell, and probably represents the largest item which could arguably be charged under the civilian head rather than entirely under defence.

The question of the work at Harwell was discussed in a debate in the House of Lords on July 5 on Lord Cherwell's motion to transfer responsibility for work on the development of atomic energy from the Ministry of Supply to a special organization more flexible than the normal Civil Service system and under the direct control of the head of the Government. Lord Alexander's reply was not altogether convincing, and the motion was carried against the Government. Without going into the arguments advanced in that debate, the picture presented in the present memorandum affords some support for the suggestion that the Department of Atomic Energy might well be turned into a separate directorate responsible to Parliament, like other official scientific bodies, through the Lord President of the Council.

The memorandum gives a very clear picture of the organization of government scientific effort in Great Britain and should considerably facilitate the asking of the right questions if any policy of restriction of expenditure becomes necessary. It owes something, indeed, to the earlier statement "Scientific Research and Development" issued in April 1944, to which there is no reference in the bibliography, and it shows how complex is the problem of keeping the Government's research programme in balance. Particularly at a time of financial stringency is it essential to keep in mind two of those aspects which were stressed by the Select Committee on Estimates in its Third Report for the Session 1946–47.

It should lie well within the field of the Advisory Council for Scientific Policy to consider whether the sum appropriated for fundamental research is reasonably related to that allocated to the conduct of applied research and development, though it would require the assistance of other bodies, such as the University Grants Committee, to make such a survey. To determine whether the expenditure on fundamental and applied research is distributed in the best proportion between the several main lines of civil and military research is a task which can scarcely be undertaken except jointly with the Defence Research Policy Committee. Nevertheless, the attempt should be made, and both surveys should take full account of what is being done outside government establishments. So far as applied or industrial research is concerned, government effort should be ancillary and should be in balance with the main effort which is being made in industry itself. Resources of man-power or equipment allocated to government establishments must have regard to what is required in the industries those establishments exist to serve.

---

* Government Scientific Organization in the Civilian Field. Pp. 47. (London: H.M. Stationery Office, 1951.) 1s. 6d. net.

While, therefore, the opportunity for the Advisory Council on Scientific Policy has been amply demonstrated, it may be suggested that the Council has been over-conscious of its advisory capacity. On the question of man-power, a year ago it appeared strangely diffident in pressing for the figures required as a basis for concrete recommendations, and it is not clear from the present report that the new standing Committee on Scientific Man-power has received firm instructions. It is difficult to believe that a proposal to which the Council lends the weight of its authority would not have reasonable prospect of early acceptance, and it is to be hoped that no lack of confidence will in future deter the Council from making the firm recommendations in such matters which it is fully competent to make and which the scientific world is entitled to expect of it.

KEPLER THE MAN

Johannes Kepler

Life and Letters. By Carola Baumgardt. Pp. 209+3 plates. (New York: Philosophical Library, Inc., 1951.) 3.75 dollars.

THE main interest of this book lies in the numerous letters of Kepler which are made available for the first time in English translation. They have been selected from his very extensive correspondence so as to depict Kepler as a man rather than as one of the outstanding astronomers of all times. They reveal a very human person who suffered from indifferent health and, as a result of an early attack of small-pox, from permanently impaired eyesight; who was almost always in financial embarrassment, because his salary as imperial mathematician was constantly in arrears (which by 1627 had accumulated to 12,000 florins); who was continually persecuted because of his Protestant convictions; whose work was often interrupted by the disturbed conditions of the time; who suffered from frequent bereavements (only two of his twelve children reached maturity) and from family troubles—including the long persecution of his mother on the grounds of sorcery and witchcraft. The letter he wrote to Scultetus after the death of his wife and of his six-year-old son is a deeply moving document. In very different vein is the amusing letter to Baron Strahlendorf, after he had decided to marry again, describing how difficult it was for him to make a final choice, even with advice from various friends, from among eleven candidates.

In the preface of the book it is stated that this biography of Kepler is the most detailed yet presented to the English-reading public. There is indeed a great need for a comprehensive biography of Kepler in English; this book does not meet that need. The biographical portions are very sketchy; the account of Kepler's scientific work is quite inadequate, and no attempt is made to assess its value. With Kepler a mystical conception of the universe was combined with real scientific insight. Thus, on one hand, in his "Mysterium Cosmographicum" he sought for a relationship between the number and distances of the planets and the five regular solids, convinced in his own mind that there must be an abstract intelligible connexion; on the other hand, he produced works of the greatest importance, such as his "Astronomia nova", in which the first two of his famous laws were formulated, and the "Epitome astronomiae Copernicanae", in which emphasis was placed on physical causes and not on arbitrary hypotheses. His third law was enunciated in the "Harmonica Mundi", the main theme of which was to establish an elaborate system of celestial harmonies. Nor is any indication given of how Kepler patiently tried and discarded one hypothesis after another in the attempt to find one that would accord with Tycho Brahe's observations of Mars, until at last he made the momentous discovery that its orbit was an ellipse, so for the first time breaking away from the old Aristotelian conception that the movements of the planets must be compounded of circular motions.

Kepler's interest in astrology was no doubt bound up with his mystical ideas of the universe; he believed that there was an element of truth in it, although it needed to be purged of gross errors. But his 'prognostics' were prepared with his tongue in his cheek; shrewd common sense often enabled him to guess what was likely to happen, so that he gained considerable credit with the vulgar. He was thus able to alleviate to some extent his financial difficulties. In a letter to Mästlin he wrote: "Forgive me, my best teacher. There is much I must apologize for or it would damage my reputation in your eyes. The matter is this: in this calendar I do not write for the large crowd nor for scholars (with a few exceptions) but for noblemen and the prelates, who pretend to have a knowledge about things which they do not understand . . . thus hoping that the readers may be tempted to approve a raise in my salary, which has not yet been increased, just as my expenses have not yet been refunded." Many years later, when writing to Matthias Bernegger about Jakob Bartsch, who was a suitor for the hand of his daughter Susanna, Kepler remarked, "One thing I do not like, he anchors his studies in astrology".

Kepler was in Linz in 1626 when it was besieged, and a sidelight on the conditions during the siege is given in another letter to Bernegger: "With the help of God and his angels, I have survived the siege for fourteen days safely. I did not starve either, even without tasting horse-meat. Only a few had the same good luck." In these more civilized days there are queues often to be seen waiting to obtain horse-meat for human consumption!

Desperate as Kepler's financial straits often were, he repulsed the repeated efforts to induce him to become a convert to Catholicism, although that would have been of great material advantage to him at the Imperial Court in Prague. In a letter to the Jesuit Guldin he wrote that, rather than become a Catholic, "I am prepared to renounce the reward offered to me at present, to which his Imperial Majesty has graciously consented, and to relinquish even the Austrian countries, the whole Empire, and what weighs so much more than all this, astronomy itself. I would add, also, life itself."

It was to the rigours of a journey on horseback from Sagan to Regensburg in stormy wintry weather that Kepler succumbed. The journey was made in an effort to obtain from the Reichstag in Regensburg the salary which had been repeatedly promised to him and which was so long overdue. His last days were described by an unknown scholar named Fischer: "During the recent meeting of the Reichstag Kepler arrived here on a skinny mare (which he sold later for two gulden). He had been here for just three days when a fever befell him. . . . Soon it increased so that he lost consciousness. As long as the illness lasted, he did not talk like one in possession of his mind. . . . On the 19th [November, 1630] he was buried in the cemetery of St. Peter's, outside the town. For it is not the custom to bury Lutherans inside the walls."

His friends erected a tombstone over his grave with an epitaph he had himself composed:

Mensus Eram Coelos Nunc
Terrae Metior Umbras
Mens Coelestis Erat
Corporis Umbra Iacet.

But within three years the stone was destroyed when Regensburg was conquered by the Duke Bernhard of Weimar in the course of the Thirty Years' War.

This picture of Kepler the man is a valuable contribution to astronomical literature and is of absorbing interest. H. Spencer Jones

---

RECENT RESEARCHES IN PHYSICS

Physical Society

Reports on Progress in Physics. Vol. 13 (1950). Pp. iv+424. (London: Physical Society, 1950.) 50*s*. net; to Fellows, 25*s*. net.

"Reports on Progress in Physics", the series of annual reports on recent advances in physics, inaugurated in 1934 and published by the Physical Society, is now an established part of our scientific literature and needs no special introduction or recommendation. It is sufficient to say that Volume 13 is of similar high standard, both in subject-matter and in production, to that of previous volumes in the series. Nine separate topics, covering mainly the experimental field, are chosen for individual treatment in Volume 13. They range from the very border-line subject of physiological optics to the fundamental physics of magnetism.

Three articles deal with various aspects of astronomy. Recent advances in infra-red solar spectroscopy are reviewed by L. Goldberg of the McMath–Hulbert Observatory of the University of Michigan. The way in which the infra-red spectrum between 0·8 and 3·6 μ has been recently mapped, at the Observatory and at Mount Wilson, with a resolution comparable with that which can be obtained photographically, is described. Lead sulphide photoconductive cells and a high-dispersion grating spectrometer were used. It is stated that an atlas of the spectrum, consisting of approximately 250 of the Mount Wilson tracings, each about 70 A. in length, and covering the wave-length region 0·8–2·5 μ, is being published. The post-war developments in radio-wave spectroscopy in the range of wave-lengths of 1 cm.–15 m., particularly the work carried out at the Cavendish Laboratory, Cambridge, are admirably described by M. Ryle of that Laboratory in an article entitled "Radio Astronomy". A shortened and slightly modified version of this report appeared under the same title in the February 1950 issue of *Physics Today*. The report is complementary to the recent excellent surveys of J. S. Hey (*Mon. Not. Roy. Astro. Soc.*, 109, 179; 1949) and J. L. Pawsey (*J. Inst. Elec. Eng.*, Pt. 1, 97, 290; 1950), and therefore more emphasis has been placed on the limitations of the experimental techniques and of the theoretical implications of the observations. Spectroscopic, visual and photographic observations of planetary atmospheres are discussed by G. P. Kuiper, of the Yerkes Observatory, University of Chicago. This article is illustrated by some very fine photographs, taken at the Lowell Observatory, of the planets Mars, Jupiter and Saturn.

Electrostatic generators and linear accelerators were the subjects of separate reports in Volumes 11 and 12 respectively of the Reports. To complete the series, in Volume 13 there is a clearly written and well-illustrated article by J. H. Fremlin and the late J. S. Gooden on particle accelerators, such as the cyclotron, betatron, etc., in which magnetic fields are used for controlling the particle orbits. It is natural to turn from this article with its description of what the new, extraordinarily costly and extraordinarily powerful synchrotrons and synchro-cyclotrons are capable of doing, to the last report in Volume 13, where Prof. C. F. Powell gives an account of the production of mesons in the atmosphere as a result of cosmic radiation, for, as Powell remarks, "even when the new machines have been brought successfully into operation it will still be necessary to turn to natural sources in order to study the nuclear transmutations produced by particles of the greatest energy". The nuclear physicist will regard Powell's and Fremlin and Gooden's reports as of paramount importance.

The longest report, a hundred pages, in Volume 13 is by Prof. E. C. Stoner and is the second half of his survey on ferromagnetism, the first half of which appeared in Volume 11. Under the composite title of "Magnetization Curves", the magnetic properties of single crystals, domain structure, the analysis of magnetization curves, and magnetic materials are treated. The theoretical and experimental work of the past sixteen years is adequately and exceptionally clearly described. There is no need to stress that where magnetism is concerned Prof. Stoner is a master of his subject; but it is worth while commenting that every physicist ought to read this article if only to study the elegant and exemplary manner in which Prof. Stoner collects and marshals his material and writes a technical paper.

Relaxation effects in paramagnetic crystals is the subject of the other report on magnetism in the volume. Experimental methods, namely, absorption measurements at radio frequencies, dispersion measurements and measurements at liquid helium temperatures, and their application to the measurement of magnetic specific heats, are briefly described. In the remaining two articles border-line subjects are dealt with. "Shock Waves and the Propagation of Finite Pulses in Fluids", by W. G. Penney and H. H. M. Pike, is based on work done during the Second World War and contained in papers only recently declassified or still unpublished, and should be extremely useful to workers in this field. "The Investigation of Eye Movements", by M. P. Lord and W. D. Wright, will be of interest to ophthalmologists, psychologists and physiologists as well as physicists.

Attention must be directed to certain changes which have been made for Volume 13. The Reports have been placed under the general supervision of the Papers Committee of the Physical Society, with Dr. A. C. Stickland as executive editor; the detailed name index has been discontinued, and a contents list has been provided at the commencement of each Report. The reviewer regrets the absence of abstracts, but welcomes the announcement that it is proposed to supplement the cumulative name index for Volumes 1–7, already published, by a cumulative index for authors and subject-matter for all the volumes up to date.

AMERICAN RESOURCES

Conservation of Natural Resources

Edited by Guy-Harold Smith. Pp. xii+552. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 48s. net.

"RESEARCH Conservation" now appears in the curricula of many American universities. It is an indication of the increasing realization that the natural resources of the world in general, and the United States in particular, are far from being inexhaustible, and that serious attention should be paid to their conservation.

The subject as taught in the universities is, in fact, economic geography, dealing in turn with each of the main products required by man, but to which is now added an assessment of reserves and an account of the steps which are taken or should be taken to maintain supplies, so leading into the field of State and local planning.

The book under review deals exclusively with the United States and is the co-operative effort of twenty authors under the general editorship of Prof. Guy-Harold Smith, professor of geography in the Ohio State University. It is divided into eight parts, comprising twenty-three chapters. The first chapter, by A. J. Wright (Ohio State University), deals appropriately with the development of conservation in America, and is followed by Chapter 2, "The Public Domain and its Disposal", by S. S. Visher (Indiana University).

Nearly every visitor from the Old World to the New is struck at once by evidences almost everywhere of profligate waste of land and resources. In Britain where the total area of land of all sorts is only a little more than one acre per head of population, conservation has been automatically a part of the British way of life for many centuries. It is difficult to appreciate what has happened in the United States over the past hundred years, where the exposure of vast tracts of former forest and grassland to the evils of soil erosion by indiscriminate clearing and ploughing has led to the abandonment of millions of acres. It is greatly to be hoped that the evils of the present position there will be fully appreciated before the same forces of destruction are let loose in the so-called under-developed lands of Africa and South America.

Part 2, occupying a major part of the book, deals with soils, soil conservation, tree crops, irrigation, grassland, marsh-reclamation and the agricultural prospect. Part 3 deals with forests, Part 4 with water in its different aspects, Part 5 with minerals, including fuel, Part 6 with wild life and fisheries. Part 7 comprises a chapter on recreational resources and a chapter by the late Ellsworth Huntingdon on the conservation of man and what he called the "geography of the human crop". He draws the conclusion that at present the quality of the American people is declining and that little attention is being paid to the decline. Finally Loyal Durand (Tennessee) deals with State and local planning, and the editor with national planning and the conservation of resources. He rightly stresses the continuing need for research and refers to the United States as a country of diminishing material resources, but where there are still new frontiers to be explored. The United States is passing from the phase of extensive, carefree use of land, to an intensive, careful one.

This volume is a scholarly, objective and timely survey of the whole field; it is fully illustrated by maps and diagrams and adequately documented.

L. Dudley Stamp

SCIENTIFIC PHOTOGRAPHY

Wissenschaftliche Photographie

Eine Einführung in Theorie und Praxis. Von Prof. Dr. E. v. Angerer. Vierte Auflage. Pp. vii+226. (Leipzig: Akademische Verlagsgesellschaft Geest und Portig K.-G., 1950.) 13.80 D. marks.

Photography in Astronomy

By Dr. E. W. H. Selwyn. Pp. 112. (Rochester, N.Y.: Eastman Kodak Company, 1950.) 2.75 dollars.

CONSIDERING the wealth of fundamental physical and chemical problems underlying photographic practice, and the many diverse fields of research in which photography is such a valuable—sometimes an indispensable—tool, it is remarkable that there is such a dearth of good general texts on the subject in the English language. In the opinion of the reviewer this is closely connected with the neglect of photography as a subject of study, whether from the scientific interest of its underlying theory or as a branch of technology deserving of scientific analysis, in British universities and higher technical colleges. Certain it is that the position has long been different in Germany and Austria, as the mere mention of such names as Eder, Luppo-Cramer and Luther will serve to remind us.

The author of "Wissenschaftliche Photographie" is an associate professor at the Technische Hochschule at Munich, and his well-known book (first published in 1939) is a good example of the sort of text we need. Its virtues lie especially in its method of approach to the subject—an approach calculated to appeal to the serious student, and to the research worker who wants something more than a 'cookery book' to guide him in his use of photography as a tool. Yet it is not an exhaustive text by any means, but only an introduction to the subject; and for this reason, perhaps, this fourth edition does not differ very markedly from earlier editions. It is excellently produced and moderately priced.

In the absence of academic texts in English, the photographic industry itself has sought in recent years to fill the gap: Dr. C. E. K. Mees's "Theory of the Photographic Process" and Dr. Walter Clark's "Photography by Infra-Red" will come to mind in this connexion. Dr. Selwyn's book on astronomical photography is another excellent, though slender, text from the same source. It is essentially readable, superbly illustrated, and very well produced; and the fact that it comes from one particular industrial company is not obtrusive. The astronomer may find it a useful summary, the student in other fields will certainly learn much from it; but both will no doubt regret its omission of references to original work.

L. V. Chilton

Statistics

An Intermediate Text Book. By Dr. N. L. Johnson and H. Tetley. (Published for the Institute of Actuaries and the Faculty of Actuaries.) Vol. 2. Pp. xi+318. (Cambridge: At the University Press, 1950.) 20*s*. net.

STATISTICS is now an important part of the course of training for actuaries. The Institute of Actuaries and the Faculty of Actuaries have consequently arranged for the preparation of this book for the use of their students.

This second volume, which completes the work, has three chapters on the general theory of distribution functions, their application to particular types of sampling and the multinomial distribution (leading to χ^2). There follow chapters on the general theory of statistical tests and estimation, stratified population and variance analysis, correlation analysis and curve fitting, and graduation. The exercises at the end of each chapter and the end of the volume are numerous and well chosen. That the book emanates from the Cambridge University Press is sufficient guarantee of the quality of the printing; and the price, in present circumstances, is quite reasonable.

The defects of the book—it is perhaps scarcely fair to describe them as such—are inevitable in any attempt to compress statistical theory into a comparatively brief compass at the University Intermediate level. There is only space, for example, for two and a half pages on least squares estimation, and less than that for maximum likelihood. On the other hand, there are sections on topics which have not yet found their way into standard texts, such as the supplementation of the χ^2 test by tests of changes of sign. Notwithstanding the limited objective of the book, it should also form a useful Intermediate text for non-actuarial students.

Trace Elements in Plants and Animals

By Prof. Walter Stiles. Second edition. Pp. xi+189+8 plates. (Cambridge: At the University Press, 1951.) 15*s*. net.

THE demand for a concise and reliable account of the part played by trace elements in the nutrition of plants and animals is shown by the issue of a second edition of Prof. W. Stiles's useful book on the subject. The text remains for the most part unchanged, though a number of supplementary references and a photograph illustrating molybdenum deficiency in cauliflower have been included. In view of the rapid progress that has been made in this field it seems a pity that the opportunity was not taken to extend the section on molybdenum deficiency in plants a little further, and that no references later than 1948 have been quoted. K. W.

Flora of Egypt

Vol. 2: Angiospermæ, part Monocotyledons; Cyperaceæ–Juncaceæ. By Vivi Tackholm and Mohammed Drar. (Fouad I University: Bulletin of the Faculty of Science, No. 28.) Pp. xii+547. (Cairo: Fouad I University Press, 1950.)

NINE years have elapsed since the publication of the first part of this work. The second volume covers the sedges, palms, aroids, rushes and some related families. The Flora is considerably more comprehensive in scope than most works of its kind, for, in addition to the systematic account of indigenous plants, cultivated species and many garden plants are included. All plants of importance in Egypt, either because of the uses to which they are—or used to be—put, or because of their connexion with ancient cultures, receive an unusually detailed treatment which embodies much historical, archæological and other information of interest and value. There are also copious references to literature relating to all the aspects discussed. Particularly detailed accounts are given of papyrus and date palm, in which the importance of these plants is described in relation to art, literature, religion and ancient industries. It is therefore not surprising to find that, in this volume of more than 500 pages, only seventy native species are included. The account of the palm family, for example, runs to nearly 200 pages, though only the date, dom and argoun palms are extensively grown and are important species, and only one of these is indigenous. The many other exotic species included are all cultivated plants. It is greatly to be hoped that future parts will appear at more frequent intervals, and that it will be possible to complete the work on the scale and with the thoroughness foreshadowed by the first two volumes. W. A. S.

Die naturwissenschaftliche Illustration

Ein geschichtlicher Überblick. Von Claus Nissen. Pp. 64. (Bad Munster am Stein: Lothar Hempe Verlag, 1950.) n.p.

THIS little book surveys a very large subject—the history of animal and plant illustration from classical to modern times. Such a work must deal with questions of art, illuminated MSS., the evolution of the printed illustration, the woodcut, line engraving and etching on copper, lithography, and finally the numerous processes based on photography by which illustrations in black and colour can be produced. It is obvious that a small octavo booklet of only fifty-six pages can only explore so vast a field in the merest outline. Dr. C. Nissen's contribution, however, will be very useful to the beginner in setting him on the road to more detailed information. Skeleton bibliographies are added. F. J. C.

The Subject Index to Periodicals, 1949

Issued by the Library Association. Pp. xi+296. (London: Library Association, 1951.) 105*s*.

SINCE the outbreak of war in 1939, the "Subject Index to Periodicals", of which the 1949 volume has now been published, has dealt only with periodicals in the English language, which are published in Great Britain, the Dominions and the Colonies, excluding Canadian periodicals, which with American periodicals are adequately covered by the H. W. Wilson Company's indexes. Highly specialized periodicals in science or technology are also omitted and the "Subject Index" thus caters chiefly for the general reader, offering him a key to the contents of many periodicals which are not indexed elsewhere. Among these are some devoted to subjects of limited appeal such as stained glass or mountaineering, and also the proceedings and transactions of local societies concerned with antiquities, natural history, etc. The "Subject Index" is compiled on the plan of the 'dictionary catalogue', all entries being in simple alphabetical order. Articles relating to people, places, institutions, etc., are placed under the proper names in question, while 'subject' articles are entered under simple, practical headings, which describe, as specifically as possible, the material in question. Cross-references are freely used for linking up related subjects, and where necessary titles are elucidated by admirable explanatory annotations. The production and layout maintain the high standard set by previous volumes of the "Subject Index".

AURORAS AND LUMINOUS NIGHT CLOUDS*

By J. PATON

Department of Natural Philosophy, University of Edinburgh

Auroras

SCOTLAND is well situated for observing auroras for they may be seen there on the average on about forty nights in the year, compared with seven to ten nights in the south of England. Since 1946, four stations—at Abernethy and Blairgowrie in Perthshire, Newton Stewart in Wigtownshire and Roseneath in Dumbartonshire—equipped with specially designed cameras ($f/1\cdot25$ and focal length 5 cm.) and linked by telephone, have been used to record the forms and to determine the positions and heights of auroras that have occurred in association with the last sunspot maximum of 1947.

It is impossible to predict precisely the course of a great aurora, but what usually happens is as follows. At first, a glow, much like dawn (hence the name aurora borealis, northern dawn, which was first used by the French philosopher, Gassendi, in 1621), appears on the northern horizon, often with a warning by day 24–36 hours beforehand of a solar flare. The glow then ascends from the horizon to form an arc, the lower border of which is at a height of about 100–110 km. Of all the auroral forms, the quiet arc is the only one of which the lower border appears always at about the same height; there is no significant variation either with latitude or with local time. This fact, together with the tendency of the arc to remain quiescent for a long time, allows the determination of its geographical position by photographs from a *single* station. In fact, when such an arc appears, there is an arrangement at the Scottish stations to photograph simultaneously according to a prearranged time scheme with Prof. Carl Størmer's Scandinavian network. The geographical position of the arc may then be plotted from mid-Atlantic to western Russia, thus providing information that may be of value to the theoretical worker.

The true colour of most arcs is probably green, for a predominant line in the spectrum is the green forbidden line 5577 A. of atomic oxygen, and this happens to be in the region of maximum sensitivity of the retina. But, except in the case of very bright arcs, it appears to the eye to be grey-white, since the light intensity is below the threshold of colour perception. The arc may then brighten suddenly to an intensity above the threshold such that patches of vivid greens and reds can be seen here and there along its length. Simultaneously the lower border becomes extraordinarily sharply defined and is appreciably lower, all of which are signs that the arc is about to lose its regular shape and to show ray structure. It may then undulate to appear like the folds of a huge waving curtain, or it may take the form of a wide band, stretching irregularly across the sky. The base of these draperies may come as low as 90 km.; the minimum height tends to occur at about 0300 hr. local time, so that the particles which cause auroras appear to penetrate most deeply into the atmosphere about this time. There is some evidence, too, that the bases of curtains and bands are lower in lower latitudes. Indeed, one of the aims of low-latitude stations, such as those in Scotland, is to investigate these latitude variations.

When the rays pass overhead into the southern sky, they then form what is undoubtedly the most spectacular of auroral forms—the corona. The rays appear to converge to a point, approximately the point in the sky to which the south pole of a magnetic dip needle would point—in Scotland it is about 20° south of the zenith. Thus the direction of the auroral streamers coincides approximately with the lines of force of the earth's magnetic field. This is what would be expected if the aurora is caused by charged particles emitted from the sun at the time of the flare, for, when they eventually enter the earth's magnetic field after their journey of a day or so through space, the particles would be deflected to travel ultimately either directly down the lines of force or in close spirals round and down them. The auroral light is produced along their path by the excitation of atmospheric atoms and molecules, probably mainly by collisions with secondary electrons ejected by the primary auroral corpuscles. The light streamers are therefore closely parallel and their apparent convergence in the corona is merely the effect of perspective.

When the display is at its height, the total illumination may be greater than that of full moon. During the great display of January 25, 1949, it was possible to pick out trees and fields on a hillside three miles away. At one point during this display the illumination suddenly ceased as if the lights had been switched off; but a great display usually fades out in what is called 'flaming'—waves of light, generally of low intensity, surge upwards, one after the other, towards the zenith. Sometimes this whole sequence may be repeated. There is a fairly well-marked diurnal variation with a main maximum at 2200 hr. and a secondary one at 0400 hr. Usually, luminosity is greatest and the auroral forms are most active and well defined at the time of the main maximum, and it is then that the display is likely to reach its most southerly limit. At the time of the secondary maximum, the forms are often diffuse and weak.

The method of determining the height and position of aurora is due to Prof. Størmer, who, besides making important contributions to the theory of aurora, has, during the past forty years, made a very thorough investigation of auroral forms seen from Norway. A certain part of the aurora is photographed simultaneously by the observing stations, and then, on comparing the plates, the relative parallax of the star background is measured and the location of the aurora computed. During the great aurora of January 25, 1949, a base line of 169·8 km. was used between Abernethy and Newton Stewart to measure the height and position of red diffuse surfaces, which were found to be situated at heights of 500–700 km. over northern Germany. As might be expected, the main difficulty has been cloud and fog, which have completely obscured at least two great auroras, and often obscure an aurora at one of the stations when the others are able to make an exposure.

Luminous Night Clouds

The auroral cameras and plates are suitable for the photography of the rare noctilucent or luminous night clouds, so that when the brilliantly blue clouds were observed on July 10–11, 1949, parallactic photography was immediately begun and continued until the clouds slowly vanished in the growing light before dawn. Measurements showed that the whole mass of cloud was situated at heights between 84 and 89 km. and was confined within the twilight circle. (The greatest height at which ordinary clouds appear is about 12 km.)

---

* Substance of a paper read on August 9 before Section A (Physics and Mathematics) at the Edinburgh meeting of the British Association.

It is most surprising that the first records of these remarkably lovely blue clouds appeared as late as 1885. Their spectrum is similar to that of the day sky and shows Fraunhofer lines; the particles constituting the cloud then are so high that those within the twilight circle are in sunlight, revealing their presence by the sunlight they scatter. Their blue colour indicates that the diameter of their particles is small compared with the wave-length of light.

The conditions necessary for observation of the clouds are as follows: the sun must be at least 10° below the horizon in order that the sky background may be sufficiently dark; it must not be more than 18° below the horizon, for an appreciable part of the atmosphere above 80 km. must be in sunlight; normal clouds must be sparse or absent and visibility excellent. Thus they can be seen only in the summer months and only within latitudes 45°–62°.

The first accurate measurements were made in Germany by Jesse about 1890. He found their height to be about 79–90 km., and on one occasion recorded the remarkable velocity of 177 m. per sec. or 400 m.p.h. He observed that they travelled from the north-east before midnight and from east-north-east after midnight. They occurred frequently and in brilliant forms during 1885–88. Omond saw them from Ben Nevis Observatory on every clear night from June 4 to July 2, 1888. From then until 1932 they were seen only occasionally. During 1932–34 the clouds again appeared in brilliant forms to give Prof. Störmer the opportunity of applying the technique that he had used so successfully in studying auroras. He confirmed Jesse's measurements, finding the mean value of their height to be 82 km. and their velocities to lie in the range 48–83 m. per sec. The clouds were rarely seen between 1934 and 1949, but during and since 1949 several fine displays have been photographed and measured both in Norway and Scotland. On July 24–25, 1950, the rare coincidence occurred of luminous night clouds in association with an aurora. On this occasion the clouds soon became so brilliant that they extinguished the aurora. By 0100 hr. they extended along the horizon between azimuths 345° and 85° and reached an elevation of 25°; at this time, so brilliant were they, that it was possible to make notes and observe the stop watch by cloud light.

The nature and origin of the clouds is still uncertain. Jesse thought them to consist of the products of condensation of matter projected into the high atmosphere at volcanic eruptions; the magnificent displays of 1885–86 were ascribed to residual dust from the Krakatoa eruption of 1883. But Vestine has pointed out that just at this time there occurred a remarkable number of meteor appearances, showers and great comets. Moreover, no marked increase in the frequency of the clouds succeeded the eruption in 1912 of Katmai, Alaska, whereas the great Siberian meteor of 1908 was followed immediately by a brilliant display. So he concludes, and Prof. Störmer agrees, that the clouds consist of material of cosmic origin.

On the other hand, Vegard believes that the clouds may be formed by the condensation of water vapour on sodium oxide nuclei formed by the combination of sodium and atmospheric oxygen. He suggests that the presence at this great height of water vapour, in the concentration necessary to account for such extensive clouds, may result from the combination of atmospheric oxygen, perhaps in the form of ozone, and hydrogen, projected into the atmosphere from the sun. There is evidence that a temperature minimum of the order of 200° K. exists at a height of 80 km., and, as the pressure there is of the same order of magnitude as the vapour pressure of water, conditions may be favourable for condensation. During the display of July 24–25, 1950, portions of the clouds were observed to change colour from vivid blue to white, suggesting growth of the particles.

Now that Whipple's meteor observations and the theoretical work of others on atmospheric tides indicate that temperature falls rapidly from a maximum at 60 km. to a minimum at 80 km., the problem of explaining the occurrence of the clouds always at about 80 km. is resolved. Meteoric dust, for example, would tend to drift to and remain below the base of the inversion at 80 km., and if these are water clouds, then condensation is most likely at the temperature minimum at 80 km. Indeed, the presence of the clouds always at this fixed level is itself evidence of the existence there of a temperature minimum.

Wave formation is a characteristic of the clouds, and measurements show that the distance between the wave crests is about 9 km. Recalling the great speeds with which these clouds may travel, the wave formation is no doubt generated in the wind shear at the inversion, as in ordinary billow clouds.

These clouds are naturally of great interest to the meteorologist for, with meteor trains and now the new radio methods, they provide a direct means of measuring air movement at these high levels.

STORAGE OF FARM PRODUCTS

It is often not realized that an increase in the yield of a farm crop which has taken many years of selection and improved culture to achieve may be much less than the losses during storage of the crop. For example, it has been estimated that a fifth of the total production of potatoes in France is lost during storage because of respiration, water-loss, disease and sprouting. There seems no reason for believing that the overall loss in Great Britain is much less, in which case the weight lost during storage would be sufficient to supply the whole human population of the United Kingdom for nearly four months. Admittedly potatoes are one of the more impermanent farm crops; but for most products the development of more efficient means of storage is a matter of great importance, and clearly merited the discussion devoted to it at Edinburgh by Section M (Agriculture) of the British Association during the morning of August 10 under the chairmanship of Dr. E. M. Crowther, president of the Section.

Prof. S. J. Watson, of the Department of Agriculture and Rural Economy, University of Edinburgh, speaking first, discussed the storage of grass. The traditional method—by making hay—is extremely wasteful of the feeding potential of the grass. In a wet year as much as half the feeding value may be lost by various means—as by respiration during the comparatively slow drying process and by leaching. Even in an exceptionally fine year about a quarter of the nutrients originally present is lost. The average loss is about a third. The use of appliances, such as stakes, wires, and tripods, on which the grass is placed after cutting reduces these losses but only by about 5 per cent. On the average, ensiling without any addition is as wasteful as haymaking in an average year, though it must be remembered that silage and hay are not comparable, the former being made from younger and more leafy material. The various forms of fermentative losses during ensiling may be reduced if the *p*H is low, preferably below *p*H 4, and it has been claimed that the losses are very slight if silage is made with the addition of acid. The beneficial effect of the acid tends, however, to be local. Possibly the best practical method is to use a roofed and lined pit silo and achieve a certain degree of acidity—say *p*H 4–4·5—by the addition of molasses and the consequent lactic acid fermentation. This acidity is sufficient to suppress butyric acid fermentation.

By far the most efficient means of conserving the feeding value of grass, Prof. Watson said, is to dry it artificially. The net feeding value may be of the order of 7 per cent less than that of grass, due mainly to the greater loss of energy in the mastication of dried, as compared with fresh, grass. The disadvantages of grass drying are economic; but Prof. Watson agreed in the course of subsequent discussion that such disadvantages might not be important if the drying were undertaken on a large scale by a competent factory manager. Broadly speaking, he recommended drying for the large-scale preservation of grass and, on the small scale, ensiling in either pit silos or good tower silos. Hay would still be made, and every care should be taken to keep the losses to a minimum.

Following Prof. Watson, Mr. J. H. Leycester, of Wheatfield, Hilton, Huntingdon, described the method which he has developed for storing grain, explaining that it had been planned to meet his own requirements for the storage of about four hundred tons of wheat and barley. The system followed is not to harvest the grain moist and then dry it, but to wait for dry weather and harvest twenty tons a day using combines with a total cutter-bar length of twenty feet. The grain is delivered in bulk by pneumatic tipping lorries to the store, which consists of a receiving bin (with a floor sloping to the outlet and feeding by gravity into a pneumatic conveyor), a cleaning unit and eight 40-ton storage bins. No dryer is installed—this being a useful selling-point when disposing of the barley for malting. In years when the grain has necessarily been harvested wetter than advisable, drying down to 16·5 per cent moisture has been achieved by repeatedly passing the grain from one bin to another through the pneumatic conveyor. Passage once through the conveyor has been found to remove 0·25–0·5 per cent of moisture at a cost of 2·2d. per ton. (In answer to questions, Mr. Leycester stated that this is the cost of electricity only.) He agreed that a moisture content of 16·5 per cent is higher than normally regarded as advisable, and only exceptionally does he store grain at a moisture content as high as this. The stored grain is shifted from one bin to another during storage at intervals of 6–7 weeks, one bin being kept empty to enable this. Asked whether, in the light of experience, he could suggest improvements to his store, Mr. Leycester replied that it would be better if it were excavated to a depth sufficient to avoid the necessity for a loading ramp from which the receiving bin is now filled. Higher storage bins and a conveyor of greater capacity would be preferable.

The further proceedings of the meeting were devoted to the storage of potatoes. Mr. W. G. Burton, of the Ditton Laboratory, East Malling, of the Department of Scientific and Industrial Research, outlined the ideal conditions for the storage of potatoes but stated that these were attainable only in heavily insulated cool stores with continuous air circulation. These are not at present thought economically justifiable. Potatoes stored at normal temperatures generate sufficient metabolic heat to raise their temperature 0·6–0·8 deg. F. per day. In a stored mass of potatoes a state of dynamic equilibrium is set up in which heat removed by convective air circulation and conduction, both of which result from the difference in temperature between the potatoes and the surrounding atmosphere, just balances the heat produced by respiration. At normal storage temperatures of 40–50° F. and for unsprouted tubers it is approximately true to say that, if the width and length of an unventilated potato stack exceed twice the height, increasing them has little effect upon the average and maximum temperatures, that the average temperature of the potatoes will exceed that of the store air by ⅔ deg. F. for every foot of height; and that the maximum temperature among the potatoes will exceed the average temperature of the store air by 1 deg. F. for every foot of height. The provision of ventilating ducts beneath the potatoes lowers both the average and maximum temperatures, and further cooling is possible if forced ventilation with a power-driven fan is employed. Continuous forced ventilation at a rate of 2,300 cu. ft./ton hour will remove about 110 B.Th.U./hr. deg. F. difference in average temperature between the potatoes and the ventilating air, and with air at a steady temperature will maintain stored potatoes at an average temperature exceeding the inlet temperature of the ventilating air by about 1 deg. F. and with a maximum temperature less than 1 deg. F. higher than the average temperature. Continuous ventilation causes excessive wilting. In addition, the temperature of the outside air fluctuates widely, and is often such that ventilation serves only to warm the potatoes. By forced ventilation with cold night air it has proved possible to maintain a stack of potatoes at an average temperature fluctuating within approximately ±2 deg. F. about an average rather below the average weekly air temperature. In answer to a question, Mr. Burton stated that potatoes harvested immature will at first produce more heat than mature ones; but after storage for some weeks the heat production of immature and mature potatoes is approximately the same.

Dr. A. R. Wilson, of the Agricultural Research Council Potato Storage Unit at Sutton Bonington, described the practical advantages to be derived from the indoor storage of potatoes. He stated that a single-story building in which the potatoes are stored to a depth not exceeding twelve feet is most useful under British conditions. The potatoes should be stored in one large mass, not sub-divided into bins. Sub-division by straw bales can be used if necessary to avoid mixing varieties. Storage to a depth of about six feet in existing farm buildings is satisfactorily practised in many parts of the country, and although this method is wasteful of floor space, this need not be a disadvantage if the space is required for other purposes, such as machinery storage during the summer. Excluding such alternative uses, there is no doubt that storage to a depth of twelve feet is cheaper per ton than is shallow storage. The store should not be less than twenty-four feet wide if machinery is to be manœuvred without difficulty, nor more than thirty feet wide because of difficulties in air distribution if deep storage with bottom ventilation is practised. For storage until March sufficient insulation is provided if the walls have a transmittance value of 0·2 B.Th.U./sq. ft. hr. deg. F. difference, and, if with such walls the roof is insulated to give a transmittance value of 0·15, condensation and drip are prevented. The most efficient means of ventilation is by a thermostatically controlled power-driven fan delivering to ducts under the potatoes. Manual control usually results in less cooling and more ventilation, which latter is to be avoided because of the wilting caused. Bulk harvesting has proved more efficient than other methods, and an elevator-loader has been designed to handle potatoes in bulk. It has a hopper to receive bulk loads from standard tipping trailers and has an outreach of twelve feet when loading to a height of twelve feet. A loading-rate of twelve tons per hour has been reached over short periods, and the turn-round of vehicles with two-ton loads has been achieved in less than seven minutes. Preliminary studies on the comparative costs of clamping and indoor storage indicate that a capital expenditure of £5 per ton on storage accommodation is justifiable, even leaving out of consideration such important advantages of indoor storage as independence of weather conditions during grading. In reply to a question Dr. Wilson stated that the ventilating unit of a grain dryer can probably be used to ventilate a potato store, and, in fact, some farmers are experimenting with such dual-purpose installations using the platform-type sack dryer.

If food is produced far in excess of the need for it, its storage or wastage is a matter of indifference. At the other extreme we may have conditions such that the conservation of farm products to the greatest possible extent is an overriding necessity. For each product mentioned during the discussion, methods of storage are known which will preserve a very high proportion of the value for much longer than is normally necessary; but such methods are regarded as uneconomic under present conditions. It was clear from the discussion that the methods adopted and being sought in practice are therefore compromise attempts to preserve as much as possible within the framework of the present relative values of farm products and the apparatus necessary to preserve them.

LIMITS TO INTENSIVE PRODUCTION IN ANIMALS

On August 14 at the Edinburgh meeting of the British Association, Section M (Agriculture) held a symposium on "Limits to Intensive Production in Animals". Prof. R. A. Fisher, Balfour professor of genetics, University of Cambridge, read the first paper, taking for his subject "Genetical Limits to Intensive Production in Animals". He referred to farm animals as part of a farmer's machinery for turning material from a less valuable into more valuable form, and said that in the designing of such material the geneticist can make an important contribution. He commented on the separation of genetics and biometry as university subjects dealt with in different departments and taught to different sets of students, thus creating a difference of outlook and preventing progress: he felt that because of this unnatural separation it would be difficult in the future to find personnel with the necessary outlook, although they may be well trained in one or other of the subjects. Prof. Fisher's view is that the work on the breeding of farm animals is so technical and the precision of the biometrical determinations involved are so important that it is necessary to set up biometrical laboratories for the purpose. The genetics of farm livestock have been neglected in the development of the general subject of genetics. This Prof. Fisher attributed to several causes: the two World Wars have shaken the national economy of Great Britain, and there is also to be considered the economic revolution, which has interfered to some extent with the prospects of the older methods employed for livestock improvement. Livestock breeding is slow and expensive, and therefore has not been given its rightful place in research work; in fact, the whole subject of genetics has been left to amateurs and teachers and, therefore, it is but natural that such workers should prefer mice or birds for their work, rather than farm animals. He remarked on the work during the past forty years on *Drosophila* and claimed that these studies have done more towards an understanding of genetic improvement in livestock than have all the efforts made up to date with livestock themselves. He agreed that some beginnings have now been made on serious research work; but he wondered if public officials really think or imagine that a centre for the study of pure genetics of each of the larger species of animals could be of any importance for livestock improvement. Prof. Fisher's final remarks were: "As a last optimistic consideration, let me point out that land long fallowed is sometimes very productive; that unworked gold mines are the best gold mines. Because nothing effectual has been done, we may at least feel sure that the law of diminishing returns has not yet set in, as seems to be the case in some fields of plant improvement, and the ceiling of genetic potentiality is still a long way off."

In the discussion on Prof. Fisher's paper, Dr. H. P. Donald, of the Animal Breeding and Genetics Research Organization of the Agricultural Research Council, directed attention to the recent establishment of the Organization, the object of which is to study the genetics of livestock. The work is long-term, and results will not be available for some time to come. Dr. Donald pointed out that little publicity has been given to the setting up of this Organization, and it may be that this is the best procedure because it will be a long time before any results will be produced for application to the industry.

Further discussion centred around the efforts of practical farmers for livestock improvement, and it was claimed that, by the use of sires selected for specific qualities, improvements have been obtained in some breeds of cattle.

Dr. John Hammond, University of Cambridge, who spoke on "Physiological Limits to Intensive Production in Animals", referred to the British Friesian cow which recently attained a new world record in milk production, yielding in its lifetime nearly 120 tons of milk. He also referred to other high milk-yielding cows as illustrating that the limits of production have not yet been reached; in fact, he considered that there are no physiological limits to intensive production, provided that suitable nutrition and other environmental conditions are applied. Dr. Hammond showed by diagrams how a system of priorities operates whereby nutrition is supplied from the blood stream for the various body tissues and how the animal adjusts itself to the nutritional requirements. A balance is obtained according to the needs of the different tissues and the extent to which they are developed in the make-up of the animal; in cows in which high milk yields are being developed, the requirements for udder development are greater than those in the poorer milk yielders. He also dealt with pigs, in which he showed that, after feeding at a high nutritional level, better growth and development results if the high level is maintained.

Sir Thomas Dalling, chief veterinary officer, Ministry of Agriculture and Fisheries, took as his subject "Relationship of Animal Health to Production". He pointed out that in the absence of a healthy animal the results of attempted improvement in production may fail. He pleaded for a better understanding of the physiology of some of the important systems in the animal body, the study of which has been long neglected but is now being taken up largely through the efforts of the Agricultural Research Council. Infectious diseases must always limit increased production, and therefore a better understanding of their nature and how they spread is necessary; much attention has been given to their control throughout the world, and measures are being successfully practised. Sir Thomas referred at some length to bovine tuberculosis and the limits its presence in cattle places upon production. Research work has resulted in the application of schemes for its control, and eradication from Great Britain is now being undertaken. Venereally transmitted diseases and the value of artificial insemination in their control were also referred to. Dealing with increased yields of milk, special attention must be given to the health of the udder and the prevention of mastitis. In addition to the knowledge that certain micro-organisms play a part in the causation of mastitis, Sir Thomas referred to the necessity for adopting satisfactory husbandry and hygiene procedures to prevent injury to the udder tissues. He mentioned the necessity for regard for the health of an animal from the time it is conceived and throughout its young life; he stressed the importance of feeding colostrum to the newly-born animal. His remarks also covered the health of pigs and the need for close attention to nutrition whereby a sudden change in the bacterial flora of the digestive tract may be prevented. He gave as an example the finding of large numbers of micro-organisms of the salmonella group in the intestine, following the use of unsuitable diets. Sheep and poultry were also dealt with—the susceptibility of the former to infections with anaerobic micro-organisms, especially when in a thriving condition, and the high incidence of disease in the latter associated with high egg production.

Dr. A. S. Parkes, National Institute for Medical Research, discussed the "Preservation of Spermatozoa at Low Temperature". He showed a film which illustrated the freezing and thawing of red blood cells and spermatozoa in the presence of 15 per cent glycerol, the thawed cells being unimpaired. In the absence of glycerol the spermatozoa do not resume motility. Fowl spermatozoa so treated have been shown to retain their fertilizing capacity. Dr. Parkes thought that, with further refinements of technique, it would be only a matter of time before semen from bulls and other animals could be kept in a frozen condition and used long after it was obtained from the animal: in fact, he foresaw that an animal would be used as a sire long after its death. The results of this work have an important practical application. In artificial insemination as a method of breeding there is a heavy loss of semen, for it is not always possible to adjust supply to demand. When Dr. Parkes and his colleagues have progressed further in their studies, it is to be hoped that they will be able to show that semen from livestock can be preserved with results similar to those they have obtained in poultry; this will be an important forward step in improving livestock production by the greater use of selected sires.

ADVISORY COUNCIL FOR SCIENTIFIC POLICY

The fourth annual report of the Advisory Council on Scientific Policy[*] covers the period April 1950–March 1951 and, apart from the discussion of the implications of the Colombo Plan for the employment of scientific workers, technologists and other experts from Great Britain and of the recommendations of the Committee on Toxic Substances in Consumer Goods, which occupy the greater part of the report, covers much the same ground as the third report. In regard to scientific man-power the report notes that the rearmament programme will make particularly heavy demands for physicists, chemists and engineers. The Advisory Council admits that the views expressed in its last report regarding the supply of scientific men under-estimate the difficulty and that over a wide field the demand exceeds the available supply. It has set up a standing Committee on Scientific Man-power, on which the Ministry of Labour and National Service and the University Grants Committee are represented, to deal with the position. The membership of this and of other standing committees set up by the Advisory Council is detailed in an appendix. A particular question of scientific man-power, that relating to biologists, has been remitted to another of these committees, that on Biology and Allied Sciences, and this committee reported that while more general botanists and zoologists than can find employment as such may be graduating, there is a continuing shortage of most kinds of biological specialists, particularly of those suitable for employment by the Agricultural and Medical Research Councils and for posts overseas. It is unlikely that this shortage will be made good for several years, and it may be accentuated if the plans for economic development of under-developed areas, whether under the Colombo Plan or in other parts of the world, come to fruition and the biological work of the Colonial Service increases.

The Advisory Council recognizes the great scope for expansion of Colonial research, and that such expansion is likely to be limited by a shortage of scientific workers trained in the necessary disciplines as well as by financial stringency. It is equally concerned that the demands which the numerous agencies concerned with the development of backward areas may make upon British resources of scientific man-power cannot be met, if all the plans discussed come to fruition, without serious damage to other commitments. It emphasizes that the situation will only become more difficult if suitable undergraduates are now deterred from taking up careers in one of those fields of biology in which there continues to be an unsatisfied demand. It suggests that, where requests for scientific assistance under the Colombo Plan are referred to the United Kingdom, they should be examined, where appropriate, by the Research Councils, to see whether they could be fitted into their current programme of work, and that the men sent abroad should retain a connexion with one of the research councils or some other research organization at home so as to prevent isolation impairing the value of their work. Moreover, although facilities for training in British universities and other institutions are severely taxed and the financial provision may be curtailed, the Advisory Council thinks it important that places should be found for people sent to Great Britain under the Colombo Plan. In this way we could play an important part in the development of South and South-East Asia, and the effect of such assistance would be to cement and strengthen the relations already existing between the United Kingdom and the under-developed countries.

---

[*] Fourth Annual Report of the Advisory Council on Scientific Policy (1950–1951). Pp. 18. (London: H.M. Stationery Office, 1951.) 9d. net.

The Advisory Council's discussions on the Colombo Plan brought out three further points which are relevant to any major schemes of development in under-developed territories. First, experience has shown the value of initiating pilot schemes in the first instance, rather than full-scale work. Second, it emphasizes the importance of a historical study of the sociological and ecological effects of similar economic developments in the past, and of attempting to apply sound sociological principles simultaneously with promoting economic development. Third, although the extensive application of science could greatly improve the economic standards of these countries, so long as the population of the world continues to increase at its present rate the hoped-for improvements in the standards of life may not, in fact, occur.

On higher technological education, the present report adds very little to what was contained in last year's report. It notes that the proposal in the report of the National Advisory Council on Education for Industry and Commerce for a "Royal College of Technologists" does not meet the need for an expansion of the facilities for higher technological education. The Advisory Council reiterates the view that expansion of these facilities is essential if we are to develop a balanced supply of applied scientists of adequate calibre and training to achieve the broader and more vigorous applications of scientific methods and advances upon which our industrial prosperity so closely depends. While it rightly points out that the necessary development of technological education is a long-term process which must take more than a decade to achieve, something more might well have been expected of the Advisory Council in this important matter than a hope that an early decision will be announced.

The Advisory Council has received from its Scientific Library and Technical Information Committee a report on the needs of the national library of science and invention which is to form part of the new Science Centre in London. It is understood that the President of the Board of Trade has agreed that the Patent Office Library should be expanded to form the national reference library of science and invention, and that it will continue to serve the needs of the Patent Office. The library will cover the whole field of science and will be supported by the specialized libraries of the learned societies. The areas of its responsibility have been agreed with the Agricultural and Medical Research Councils and with the government departments principally concerned. A novel feature of the library is that it is not proposed that it should contain any scientific literature more than about fifty years old. In conformity with this plan, material which has ceased to have value for current work will be pruned in consultation with the British Museum. The library will serve working scientific men in industry and all those concerned with research and development; but it will not provide for other users, such as undergraduate students, for whom other facilities exist. The Committee's report has been approved by the Lord President of the Council and it has been passed to the Ministry of Works for preliminary planning in connexion with the Science Centre.

The Panel on Technical Information Services has now been dissolved and its responsibilities have passed to the Scientific Library and Technical Information Committee, which is now examining the recommendations in the Panel's report on technical information services in the United Kingdom. This report has since been published in the *Journal of Documentation* (June 1951).

The Advisory Council has considered the comments of the Medical Research Council and of the government departments concerned on the recommendations of the Committee on Toxic Substances in Consumer Goods. While it believes that the risk to life and health is probably small, the rapid growth of the chemical industry and needs of the food-processing industries for substitutes to replace scarce materials or for new chemicals for improving the appearance, palatability or texture of manufactured foods are accelerating the pace at which new chemical substances are being introduced into consumer products, and existing machinery for testing the possible harmful effects of these substances is inadequate. Adequate and fully effective arrangements should therefore be made by government departments for the acquisition of information about possibly noxious substances or processes which industry may contemplate using, before these are allowed to find their way into the composition or treatment of the articles concerned; but the Advisory Council agrees with the view that new legislation is not required at present, and recommends that manufacturers should be informed that they are expected to take all reasonable care to ensure that no new substances should be offered for sale if toxic effects are suspected. It also recommends the establishment of a standing committee of representatives of the departments mainly concerned, and that the Medical Research Council should retain the general responsibility of keeping the whole problem under review and of initiating research and should receive adequate financial provision for the purpose, including the development of information services. Information over the whole field of toxic substances should be interchanged with the appropriate authorities in other countries, and particularly with the Food and Drug Administration and other government agencies in the United States. The Advisory Council also thinks that it would be appropriate for the cost of a central toxicological laboratory to be borne by industry, either through subscriptions or out of fees paid by trade associations.

A Committee on Atomic Energy considered the possible industrial uses of atomic energy and their economic value. In the view of this Committee, there is a reasonable prospect that atomic power can be developed on a large scale and that the cost would not ultimately differ widely from that of coal. Successful development of an experimental atomic power plant depends largely on metallurgical development which is now proceeding, and the capital cost of an early type of atomic power station would be substantially greater than that of a coal station, although its fuel costs might be less. Development of such stations to a point when they can contribute substantially to the power resources of the country is likely to take at least a generation, and the Advisory Council emphasizes that work on the civil applications of atomic energy should not be allowed to retard inquiries into the better utilization of existing sources of heat and power.

BIOPHYSICAL STUDIES OF RHEUMATOID CONNECTIVE TISSUE

By Dr. J. H. KELLGREN and Dr. J. BALL
Rheumatism Research Centre, The Royal Infirmary, Manchester

AND

Prof. W. T. ASTBURY, F.R.S., Dr. R. REED and E. BEIGHTON
Department of Biomolecular Structure, University of Leeds

Introductory

IN rheumatoid arthritis and related syndromes, characteristic changes may be found in the connective tissue for which the term 'fibrinoid' is usually employed. This fibrinoid change occurs in minute spots scattered sparsely throughout the affected tissues; but on the elbows and elsewhere, sizeable aggregates may form which with their surrounding zones of fibrous and inflammatory tissue constitute the classical rheumatoid subcutaneous nodules.

Fibrinoid areas can often be seen with the naked eye as yellowish opaque spots in the semi-translucent connective tissue; but they can be recognized with certainty only by histological examination, when they are distinguished by the following characteristics.

Within a fibrinoid area connective tissue cells are either few or absent altogether, and the regular fibre pattern of normal connective tissue is replaced by a disorderly mesh of swollen, indistinct bundles or clumps of amorphous material. With eosin the fibrinoid area stains a more intense red than the surrounding connective tissue. Deposits of fibrin in the tissues may give rise to a somewhat similar appearance, hence the term 'fibrinoid'.

In frozen sections stained by Lillie's reticulin method and Van Gieson's stain, a fibrinoid area may show three different effects: fine silver-staining fibrils which histologists call reticulin; occasional clumps of material staining reddish-brown like normal collagen; and an indistinct refractile material which takes a yellow colour with the Van Gieson stain. In sections treated by the periodic acid – Schiff technique, the fibrinoid areas stain more strongly than normal connective tissue with the pink or magenta colour which is considered by many histologists to indicate the presence of polysaccharides. Histological evidence, therefore, suggests that a fibrinoid focus is not necessarily homogeneous but corresponds to alterations in both the collagen and polysaccharides of connective tissue.

It would be a substantial advance if these histological appearances could be correlated directly with observations at or near the molecular level, and the purpose of this communication is to present a preliminary account of such a comparison with the findings of X-ray diffraction and electron microscopy.

Methods

Owing to the random distribution and minute size of most fibrinoid lesions, the first requirement was an accurate sampling technique. To this end we obtained biopsy specimens of recently formed subcutaneous nodules from patients with active rheumatoid arthritis, and each specimen was fixed in 5 per cent formol saline and trimmed to a firm rectangular block which was then embedded in ice and cut in such a way that 10 μ–15 μ sections immediately preceded and followed a slice 1 mm. thick. The sections preceding and following the slice were stained in various ways and examined under the optical microscope, and, if they showed suitable areas of histologically well-defined fibrinoid, photomicrographs (× 8) were made. The corresponding thick slice was then washed in water and enclosed (wet) in a carrier specially adapted to the needs of a point-by-point

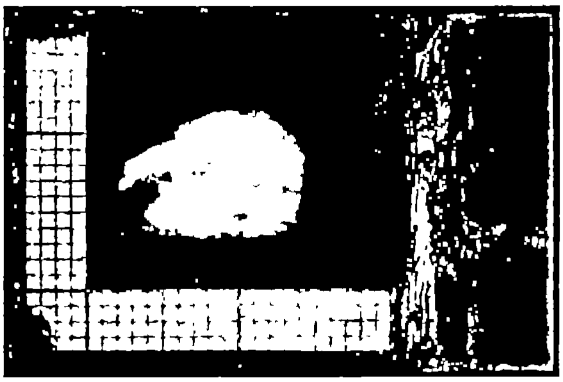

Fig. 1a. Slice of rheumatoid subcutaneous nodule mounted in carrier for exploration by X-ray diffraction

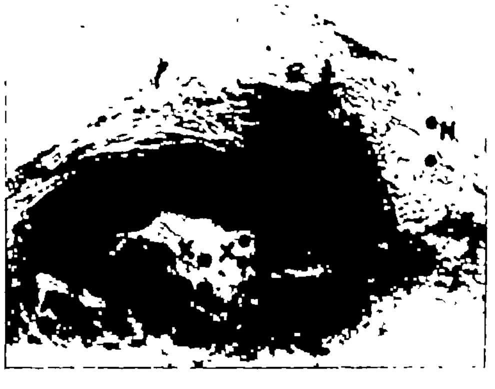

Fig. 1b. Photomicrograph of immediately adjacent section showing topographical relation between histological and X-ray examination. *N*, probably normal collagen; *I*, incipient abnormality; *X*, fibrinoid sites common to slice and adjacent sections. ●, sites of X-ray photographs

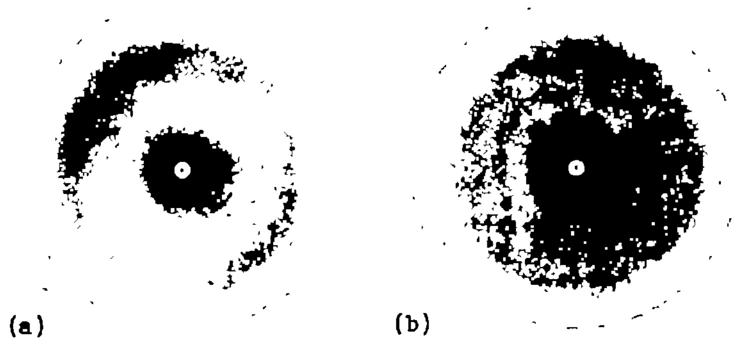

Fig. 2. X-ray diagrams of (*a*) a normal site, (*b*) a fibrinoid site in a rheumatoid subcutaneous nodule

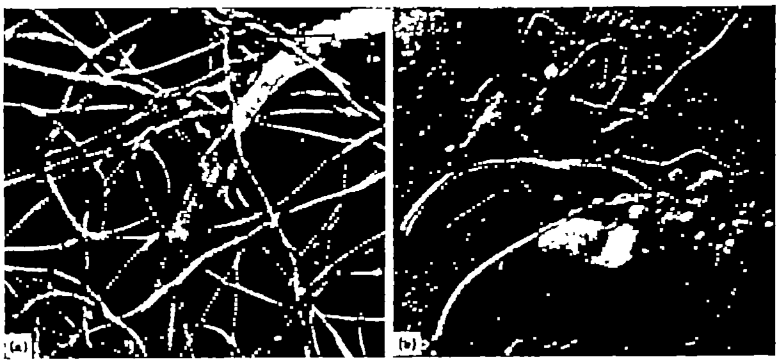

Fig. 3. Electron micrographs of (*a*) a normal site, (*b*) a fibrinoid site in a rheumatoid subcutaneous nodule. × 9,050

exploration by X-rays: it had collodion windows, and it was graduated vertically and horizontally in millimetres, so that when fitted into slides on the spectrometer the co-ordinates of the X-ray beam with respect to the slice could be read off directly for every photograph taken.

For the purpose of relating the X-ray co-ordinates to the topography of the adjacent fore-and-aft histological sections, a negative photographic plate was made of the slice in its carrier (Fig. 1*a*), and this was projected on to enlarged prints of the photomicrographs of the sections. When the best superposition of the two images had been obtained, the co-ordinates inscribed on the carrier were marked also on the prints (Fig. 1*b*).

The slice was explored with an X-ray beam ½ mm. in diameter, photographs being taken of up to as many as thirty different spots. After the X-ray study was complete, tiny fragments were dissected out from each of the same spots and examined in the electron microscope.

Results

Detailed findings will be published at a more advanced stage of the investigation, which is being planned to include an inquiry into whether there is any detectable change in the pathological collagenous tissues corresponding to the dramatic alleviation of symptoms brought about by treatments with adrenocorticotropic hormone (ACTH) and cortisone. It will suffice here to state that the sampling technique just described has proved very satisfactory indeed, and that we have found excellent correlation between the indications of histology, X-ray diffraction and electron microscopy. We have obtained two limiting X-ray diagrams: one (Fig. 2*a*) of normal collagen (often oriented and with, of course, the liquid halo in addition), corresponding to regions which histology also would specify as normal; and the other (Fig. 2*b*) consisting of little more than a diffuse ring of spacing about 4·8 A. This latter diagram we definitely associate with the histological fibrinoid regions—a poor name, by the way, since there is no recognizable X-ray evidence so far of the presence of true fibrin, for which we should expect either an α- or a β-diagram. For many of the spots examined the X-ray photographs showed both diagrams present at the same time, in general one or the other predominating in correspondence with the histological indications. In one region of a slice we found that it sufficed for the X-ray beam to be moved through only ½ mm. for the normal collagen diagram to disappear entirely and be replaced by the pure fibrinoid diagram.

The electron micrographs also revealed two limiting conditions: one of apparently normal collagen fibrils (Fig. 3*a*), and the other of amorphous material. Mostly, however, there was seen a mixture of the two, though again, in general, one or the other predominated in correspondence with the histological and X-ray indications. Fig. 3*b* is a typical picture of an intermediate state.

Concurrently with this special investigation on rheumatoid arthritis, we at Leeds have been collaborating with Prof. R. E. Tunbridge and other colleagues at the Medical School in a wider survey of pathological collagenous and related tissues. From this work it is clear that the real problem in the end is to characterize the degenerate fibrils and amorphous materials that are found so frequently in all sorts of clinically different conditions. Though they look so alike in the electron microscope, they can scarcely be the same every time, and the next step must obviously include comparative chemical analyses. We have already made a beginning along such lines in the rheumatoid arthritis problem, and we hope soon to be able to supplement our correlated histological, X-ray and electron microscope findings on slices of subcutaneous nodules with a corresponding set of micro-biochemical results.

We should like to thank Mr. G. Eaves for assistance in the electron microscopy and Mr. A. Millard for the photographic reproductions.

OBITUARIES

Prof. W. E. Agar, C.B.E., F.R.S.

Wilfred Eade Agar, emeritus professor of zoology in the University of Melbourne, died on August 14, aged sixty-nine. His health had been precarious through cardiac trouble since 1943, and he had to lead a more and more sedentary life; but he continued to work quietly in his little home laboratory up to the day before he died.

Born on April 27, 1882, at Wimbledon, Agar passed from his preparatory school to Sedbergh and then to King's College, Cambridge, where his tutor was S. F. Harmer. He went through the regular courses of instruction for the Natural Sciences Tripos, Parts I and II, in both of which he obtained a first class. Of all his teachers he looked back with special gratitude to Harmer, for his inculcation of precise and orderly method, and to Bateson, then in the flood tide of Mendelism, for turning his mind in the direction of his future research in genetics.

I had been impressed by Agar as the most outstanding member of the Tripos class in zoology during my last year as demonstrator; so when he had completed his Tripos, I invited him to join the staff of the Zoology Department in the University of Glasgow, on which he remained until 1920, holding latterly the position of senior lecturer.

During his Glasgow years, Agar showed himself to be an admirable teacher, and he also achieved a large proportion of his most valuable research work. During his first two years this was devoted to vertebrate morphology, and he produced valuable papers upon the skull and visceral arches, and upon the anterior mesoderm, of *Lepidosiren* and *Protopterus*. In 1907 he made an expedition to the Gran Chaco to supplement my work on *Lepidosiren*; but above all to obtain full material for investigating the gametogenesis of that fish—outstandingly suitable for such a research on account of the relatively enormous size of the chromosomes and their strongly marked individuality. Agar made a splendid success of his expedition and brought back a large amount of perfectly preserved material which he proceeded to investigate in detail. His skill and accuracy as an observer, in conjunction with his admirable technique, enabled him to achieve what is still probably the most reliable account of the gametogenesis of a male vertebrate. In his work he made full use of the Glasgow technique, which enjoined that all microscopic work under high-power oil-immersion objectives be done with stereoscopic eyepieces—the technique which enabled Ballantyne in 1925 to establish with certainty the passage of neurofibrils across the generally accepted discontinuity between the neurones of the vertebrate nervous system. Agar's Chaco expedition achieved other results than those of his main quest, the most important being the discovery of the 'neonychium'—the cushion-like structure which in the embryo of the Amniota fills up the concavity of the claw and safeguards the amniotic membranes against injury.

Agar's work on the chromosomes of *Lepidosiren* may be said to inaugurate the second phase of his research career, devoted to genetics. Next after it came the breeding through long series of generations of Daphnid crustaceans and having as their main object the testing of Lamarckian inheritance of environmental or 'acquired' characters. The Daphnids in question were chosen as specially advantageous for such investigations in view of their parthenogenetic reproduction, their short life-cycle, and the fact that all members of a clone are genetically identical so as to exclude the disturbing effects of Mendelian segregation. The results of Agar's work on the whole, including one particularly precise set of experiments extending over a hundred generations, was to show the complete absence of any evidence of such inheritance.

Both by his own original work and by his critical examination, and in some cases repetition, of the work of others, Agar played an important part in substantiating the view that environmental or 'acquired' characters are not inherited and are therefore not available for the process of racial evolution.

In its third phase, Agar's work diverged from the realm of pure science, in which things are observed, accurately recorded and when possible seriated into a general expression, into the realm of 'philosophy', which deals rather with ideas or opinions, and is free from the constraints to which purely scientific research is subject. In this phase Agar was, above all, influenced by the philosophy of A. N. Whitehead—primarily a mathematician, not a biologist—as expounded in his "Process and Reality". According to this philosophy, reality consists not in substance but in process, and the difference between living and non-living 'organisms' is merely one of degree—"Biology is the study of the larger organisms; whereas physics is the study of the smaller organisms." Whether or not Whitehead's philosophy is destined to have any influence upon the advancement of biological science, it is clearly of advantage to have an account of it and its implications from the pen of one who not only accepts the general principles of that philosophy but also holds a distinguished position in the realm of biological science. Such an account with further developments in detail is provided by Agar in his last book, "A Contribution to the Theory of the Living Organism" (Melbourne University Press, 1943), a revised edition of which he had just completed at the time of his death.

It would be wrong to conclude this notice without mention of Agar's activities outside laboratory and lecture-room. At Glasgow he held a commission in the Officers' Training Corps, and during the First World War he was captain in the 5th Highland Light Infantry, until invalided home from Gallipoli. Later he acted as adjutant to the 1st Volunteer Battalion of the same regiment. Then in 1920 came his appointment to the professorship of zoology at Melbourne. There he served as dean of the Faculty of Science (twice), president of the Professorial Board, in which he played an important part in the deliberations preceding the appointment of a full-time vice-chancellor, and as member of the University Council (twice).

As a Melbourne colleague writes, "Wilfred Eade Agar will be remembered by all as a thoughtful and kindly man, reserved, yet with a delightful sense of humour, slow to assert himself, yet vehement when the need arose. With his death the University of Melbourne has lost one of its great men."

JOHN GRAHAM KERR

Brigadier E. M. Jack, C.B., C.M.G.

BRIGADIER EVAN MACLEAN JACK, who died on August 10, was born in Edinburgh in 1873. Commissioned in the Royal Engineers in 1893, he served first at Gibraltar and St. Helena; and in 1903 joined the Ordnance Survey, on the staff of which he served for four years.

In 1907 he was selected for duty with the Uganda-Congo Boundary Commission under Major Bright and four years later became chief commissioner of another Central African Boundary Commission, which, in the course of its work, measured a section of the arc of the 30th meridian. In 1913, Jack, now promoted major, was posted to the Geographical Section of the General Staff at the War Office; and on the outbreak of war, in 1914, went to France with the B.E.F. as officer in charge of maps at G.H.Q. In this post, which he held throughout the War, he was responsible for directing and controlling a great variety of survey developments, including the mapping of the trench lines, German as well as British; sound-ranging and flash-spotting (for the location of enemy batteries); and, last but far from least, the 'Artillery survey' procedure, which made possible the sudden accurate bombardments of 1918 by massed artillery—a development which, from the battle of Cambrai onwards, contributed so much to the Allied victory.

For his services in the First World War Jack was awarded the C.M.G. and the D.S.O. and was several times mentioned in dispatches. The Royal Geographical Society, which in 1916 had given him its Gill Memorial Award for his work in Africa, awarded him its Founder's Medal for his geographical work on the Western Front. In 1920 he became head of the Geographical Section, and two years later succeeded Sir Charles Close as director-general of the Ordnance Survey. In 1924 he was promoted to the rank of brigadier, and in 1928 was made a C.B.

Jack retired from the Service in 1930, but this 'official' retirement was only the beginning of another career of unpaid service to many charitable and other causes, scarcely less distinguished than the one he had just completed, and which lasted for twenty years more. The kindliest and most modest of men, Brigadier Jack has left a record which any man might envy; and a memory which all his many friends will cherish.

M. N. MacLeod

Prof. E. Baldi

Prof. Edgardo Baldi died on August 10 at the age of fifty-two very much regretted by all his friends and colleagues. He was director of the Istituto Italiano di Idrobiologia at Pallanza on the Lago Maggiore, a research institute founded in 1939 which has become one of the world's leading limnological laboratories.

Baldi's research career began with work on insect neurophysiology which has left important traces in the literature. He soon turned, however, to hydrobiology, beginning with systematic work, especially on diaptomid copepods. He made a study of the distribution of the various races of *Eudiaptomus vulgaris* in Italian lakes. One of his favourite fields of research was the biology of alpine lakes, the chief object of which was to define the communities and discover their degree of temporal constancy. Rivers were also studied, the main thread of the research being the seasonal variation and survival in rivers of plankton derived from lakes.

In the last period of his life, Baldi's particular interest was in the biometrical study of form differences between planktonic Crustacea of certain species belonging to populations of varying density living in different parts of a lake. General accounts of this important part of his work are to be found in *Experientia*, 2, 476 (1946) and *Vierteljahrschrift Naturf. Ges. Zürich*, 95, 89 (1950), while details are in the *Memorie Ist. Ital. Idrobiol.* His was always the spirit of pure scientific research for its own sake. To British and other foreign biologists who had the pleasure of visiting or working in his Institute, Baldi always extended a most generous welcome.

H. Munro Fox

Dr. G. A. Shakespear

Dr. Gilbert Arden Shakespear, who died as a result of a road accident within a few days of his seventy-eighth birthday, was a prominent member of the University of Birmingham for more than half a century. Educated at Wyggeston School, Leicester, and Mason College, Birmingham, he was one of J. J. Thomson's research students at Cambridge before returning to Birmingham as lecturer under Poynting. He was acting professor during 1914–19 and, though he retired in 1938, he continued active research work in the Department of Physics.

Dr. Shakespear was distinguished for his ingenuity and skill in making precise measurements by simple methods. Much of his early work was inspired by Poynting, whom he greatly admired, and was concerned with thermal radiation. His most important contribution to science, however, arose from a practical need and was made with characteristic speed and perfection. During the First World War his attention was directed to the need for measuring the purity of hydrogen in connexion with airships and observation balloons; he quickly produced his 'katharometer', a sensitive and robust apparatus for gas analysis by thermal conductivity, and then applied it in many different directions, the principal one at that time being the permeability of rubberized fabrics.

Although the instrument has now been extensively used in measuring mixtures of many gases and in all kinds of applications, it still remains in the essentially simple form which Shakespear originally devised. The katharometer, in the hands of many workers, has been the means of making substantial contributions to many branches of science—physics, biology, physiology, medicine and chemical engineering. It is ideally suitable for measuring diffusion and thermal diffusion: it is used for measuring the respiration of plants and animals, for the control of anaesthetic gas mixtures, for the analysis of flue gases and the exhaust gases from internal combustion engines, and in ammonia plants. An indication of Shakespear's ingenuity and breadth of interest is given by the fact that with only a slight modification he was able to convert the katharometer into a very sensitive extensometer.

Shakespear was always most generous in freely giving his ideas to others. He delighted in having problems brought to him and in assisting in their solution. For this he wanted no recognition or reward; his pleasure lay in sharing in the enthusiasm for any subject and in sowing the seed of progress. His influence has thus been much greater than can be measured by the volume of his published work.

In his teaching, Shakespear was remarkable for his originality and freshness of approach on the experimental side of his subject. A student's measurement of the acceleration due to gravity in the elementary laboratory was to him a matter of importance and excitement, in which the result really mattered.

Shakespear was a man of extraordinary activity, both mental and physical, and an uncommonly keen observer of everything that lives and moves, as well as of the inanimate things. His wife, the late Dame Ethel Shakespear, was a geologist and a notable figure in the public life of the Midlands. Their farm, garden and laboratory at Caldwell Hall, near Bromsgrove, formed an ideal centre for a rare breadth of interests.

NEWS and VIEWS

Botany at Birmingham: Prof. W. Stiles, F.R.S.

Prof. W. Stiles has retired from the Mason professorship of botany in the University of Birmingham, which he has held since 1929. He moved to Birmingham after occupying the chair of botany at Reading for ten years. He has brought renown to his Department, both by his own published papers, reviews and books, and by the direction or stimulation given to the physiological researches of his colleagues and students, especially in the fields of permeability, the salt relations of plant tissues, and respiration. The way was prepared in the first field by early work done in the University of Leeds, where he collaborated, first with Mr. I. Jørgensen and, later, with Dr. Franklin Kidd. They developed the method of placing representative samples of disks of storage tissue under selected and controlled conditions. This technique for obtaining reproducible results is now widely used in many types of investigation.

Throughout his career, Prof. Stiles has favoured the use of physical instruments for measuring plant performance. In more recent times, skilled work has been performed in his research school with the katharometer in studies on respiration, and with the spectrograph, polarograph and absorptiometer in measuring small amounts of ionic absorption. Exact quantitative data have been obtained for physiological performances, controlled in the light of existing knowledge. Certain passages in his presidential address delivered in 1938 to Section K (Botany) of the British Association make it clear that no one knows better than Prof. Stiles that this knowledge is incomplete. However, he has helped to make it more ample than it was forty years ago. Moreover, no one in Great Britain has ever done more in bringing together scattered literature and making widely known major advances in knowledge of plant physiology as these occurred. We may note his review articles which have appeared regularly in *Science Progress* since 1927, and his books on "Carbon Assimilation" (1917, with I. Jørgensen), "Permeability" (1924), "Photosynthesis" (1925), "Respiration" (1932, with W. Leach), "An Introduction to the Principles of Plant Physiology" (1936, second edition 1950), and "Trace Elements in Plants and Animals" (1946, second edition 1951).

Prof. E. J. Maskell, F.R.S.

Dr. E. J. Maskell, reader in plant physiology in the University of Cambridge and Fellow of Emmanuel College, has been appointed to succeed Prof. W. Stiles in the Mason chair of botany from October 1. After a distinguished academic career at Cambridge, interrupted by service in the Friends' Ambulance Unit, 1915–19, Dr. Maskell, as Frank Smart student, carried out researches under the late Dr. F. F. Blackman on carbon assimilation with particular reference to stomatal control. In 1922, Dr. Maskell was appointed plant physiologist at the Cambridge Horticultural Station. Two years later he moved to Rothamsted Experimental Station in the same capacity, where he worked on problems of crop growth and methods of field experimentation. In 1926 he went to Trinidad as plant physiologist at the Cotton Research Station, where, in association with Dr. T. G. Mason and Dr. E. Phillis, he carried out notable investigations on the transport of carbohydrates and other solutes in the cotton plant. In 1930 he was recalled to Cambridge as lecturer in plant physiology, afterwards becoming reader and head of the sub-department in this subject in the Botany School. Since his return he has taken a prominent part in teaching and research, chiefly on the metabolic aspects of plant physiology, and many students have carried out investigations under his direction. He was elected a Fellow of the Royal Society in 1939. He returned to Trinidad for the summer of 1950 and assisted in the researches proceeding at the Imperial College of Tropical Agriculture on the mineral nutrition of the cocoa plant. Dr. Maskell has had much experience of university and college administration, and served for a considerable period on the General Board of the Faculties. Birmingham is fortunate in securing the services of Dr. Maskell, and he will be greatly missed by his colleagues in the Cambridge Botany School.

Scientific Civil Service: Promotion of Individual Research Workers

It is announced that further special posts are being created for individual research workers of exceptional merit. The promotions will be effective from January 1, 1952.

Deputy Chief Scientific Officers:

Dr. E. Glueckauf

Dr. E. Glueckauf, an outstanding physical chemist who during the pre-war period made notable contributions in surface phenomena, radiochemistry and in the measurement of the constituents of the atmosphere. Since joining the Atomic Energy Research Establishment his researches have included solution chemistry and the study of chromatography and ion exchange.

Mr. N. W. Pirie, F.R.S.

Mr. N. W. Pirie, of Rothamsted Experimental Station, is well known for his work on the separation and biochemical properties of substances of diverse biological origin and high molecular weight. The group includes antigens from *Brucella melitensis* and *B. abortus*, agar, several plant viruses, hyaluronic acid and proteins from the normal leaf. The last has been studied both on the laboratory and on the industrial scale. Most of these substances have been shown to be heterogeneous, and he has emphasized the importance of looking on macromolecules, even when they have a defined biological activity, as categories rather than as chemical individuals.

Dr. H. G. Thornton, F.R.S.

Dr. H. G. Thornton, of Rothamsted Experimental Station, has investigated many aspects of the life of the nodule bacteria and their symbiosis with their host legume, including their behaviour in soil, the process of the root infection, the growth and decay of the nodule and the structure of nodules ineffective in fixing nitrogen. With P. S. Nutman and J. H. Quastel he took part in the early experiments on the selective toxicity to plants of 2,4-dichlorophenoxyacetic acid. He has made quantitative studies of the soil microflora, and in this field he has devised improved counting methods.

Senior Principal Scientific Officers:

Mr. J. E. Gordon

Mr. J. E. Gordon, a research engineer at the Royal Aircraft Establishment, whose work has been directed towards the use of plastic structural materials for aircraft. This has involved fundamental work on structural plastics and the development of suitable plastic materials and manufacturing techniques. As a result of this work it has been demonstrated that large aircraft structures can be made cheaply and easily from reinforced plastics, and that such structures will compete successfully with the more conventional metal structures.

Dr. C. C. Hall

Dr. C. C. Hall, of the Department of Scientific and Industrial Research (Fuel Research Station), a chemist who has specialized on problems concerned with the production of oils and chemicals from coal, and is a recognized authority on the subject. He has made notable contributions to knowledge of the mechanism of the reactions in the hydrogenation of coals and tars and in the synthesis of hydrocarbon oils and waxes from carbon monoxide and hydrogen. He has played a leading part in the C.I.O.S. investigations of German researches in this field, and of the commercial plants in Germany for the production of oils and chemicals from coal; and he has been in close touch with the work of the U.S. Bureau of Mines on synthetic liquid fuels.

Dr. L. Pincherle

Dr. L. Pincherle, who joined the Telecommunications Research Establishment, Malvern, in 1948, after a distinguished academic career. Since this date he has been engaged in a study of the electronic properties of semiconductors using the methods of quantum mechanics. He has been largely responsible for initiating an extensive calculation of the electronic wave functions in ionic crystals having cubic symmetry, and has been responsible for the development of powerful mathematical methods to enable this to be achieved.

Dr. D. G. Tucker

Dr. D. G. Tucker, of the Royal Naval Scientific Service, who has had wide experience in telecommunications. For many years he was at the Post Office Research Station, Dollis Hill, before joining the Admiralty. His many valuable publications on important electronic problems give some indication of his ability as a research engineer, and the theoretical and practical work he is now doing on underwater problems is of particular concern to the Royal Navy.

Royal Aeronautical Society: Awards

The following medals and prizes have been awarded by the Council of the Royal Aeronautical Society: *Society's Gold Medal:* W. G. A. Perring (posthumously), in recognition of his distinguished service to aeronautical science; *Society's Silver Medal:* S. B. Gates, for outstanding work on the stability and control of aircraft; *Society's Bronze Medal:* H. J. Pollard, for his many contributions to the development of aircraft construction; *British Gold Medal:* A. E. Russell, for practical achievement in aircraft design; *British Silver Medal:* Group Capt. J. Cunningham, for his outstanding achievements as a test pilot; *R. P. Alston Memorial Prize:* R. J. Falk, for his outstanding work in the testing of British delta-wing aircraft; *George Taylor (of Australia) Gold Medal:* R. E. Bishop, for his paper on "Design for Maintenance"; *Simms Gold Medal:* Dr. G. S. Hislop, for his paper on "Investigation of Gusts"; *Herbert Ackroyd Stuart Memorial Prize:* A. V. Cleaver, for his paper on "Rockets and Assisted Take-off"; *Eduard Busk Memorial Prize:* R. Hills, for his paper on "The Use of Wind Tunnel Model Data in Aerodynamic Design"; *Orville Wright Prize:* Dr. Neumark, for his paper on swept-back wings, published in the *Aeronautical Quarterly*, August 1950.

National Institute of Sciences of India: Research Fellowships

The National Institute of Sciences of India has recently awarded the following research fellowships (normally tenable for two years) for work in particular fields at the places shown. *National Institute of Sciences Senior Research Fellowships:* Dr. A. M. Naqvi (solar problems), University of Delhi; Dr. S. C. Shome (corrosion of metals), National Metallurgical Laboratory, Jamshedpur; Dr. B. G. L. Swamy (comparative plant morphology), University of Madras. *National Institute of Sciences Junior Research Fellowships:* D. Basu (statistics), Indian Statistical Institute, Calcutta; Dr. M. Datta (statistical physics), University of Calcutta; Dr. A. M. Mehta (biochemistry), Haffkine Institute, Bombay; Dr. A. K. Mukherjee (bacteriology), Indian Institute for Medical Research, Calcutta; Dr. (Mrs.) T. S. Sarojini (mycology), University of Madras; E. G. Silas (zoogeography), University of Madras; T. B. Sinha (entomology), University of Allahabad. *Imperial Chemical Industries (India) Research Fellowships:* Dr. B. K. Banerjee (physical chemistry), Indian Association for the Cultivation of Science, Calcutta; Dr. A. Ganguli (plant pathology), Bose Research Institute, Calcutta; Dr. P. T. Rao (spectroscopy), Andhra University.

Graduateship of the Institute of Physics: A New Grade

A booklet recently issued by the Institute of Physics, and which may be obtained free, on request, sets out the regulations and syllabuses for the examination for the graduateship grade of membership of the Institute. This new grade was formed in September 1949 and is for those who hold a recognized degree or other qualification in physics but who do not possess the necessary period of professional experience required for the associateship of the Institute. By July of this year more than four hundred applicants had been elected to graduateship. At the moment, such applicants are only admitted if they possess an honours degree of a British university; but for those who are without this qualification an examination, starting in 1952, is being arranged. Candidates for this examination will normally be required to have followed a suitable course of study at a college or other place of learning recognized for this purpose by the Institute, those already approved including all the universities and university colleges in Great Britain, a number of Commonwealth and foreign universities, and thirty-six technical colleges in Great Britain. The subjects of the examination are physics (three papers and a practical examination), mathematics (two papers), and a third subject (one paper) chosen from applied physics, more advanced physics, mathematical physics and statistics; those choosing applied physics will be required to offer only one of the sections, electronics, high-vacuum technology, acoustics, spectroscopy, X-rays or temperature measurement. Those who already have certain qualifications may be exempted from various parts of the examination. Graduates of the Institute, who must have reached the age of twenty-one, are entitled to use the abbreviation Grad.Inst.P. The grade is non-corporate and is intended to be the normal step to associateship of the Institute.

Soil and Climatic Factors in Plant and Animal Nutrition

THE first of the specialist conferences, recommended by the British Commonwealth Scientific Official Conference of 1946, was held in Australia in 1949 to consider "Plant and Animal Nutrition in Relation to Soil and Climatic Factors". A general report of the proceedings appeared in 1950; but the papers presented, together with the recommendations and resolutions passed, have now been published in full (pp. 490. London: H.M. Stationery Office, 1951; 20*s*. net). The various aspects considered cover a wide field, and some idea of their scope may be obtained from the titles of the five sessions held: review of present knowledge of the climatic and soil factors affecting nutrition of plants and animals; effects of specific soil and climatic factors on the nutrition of plants; nutritional problems of the animal as determined by plant and soil; pasture management; and influence of plant and animal on soil fertility. From the papers presented, it is evident that a wealth of information has already been obtained in each field; but in its recommendations the conference stresses the necessity for closer co-ordination of research if full use is to be made of the knowledge acquired and the gaps in that knowledge filled. In particular, the need for co-operation is urged between, on one hand, specialists in soil science, agronomy, plant physiology and biochemistry and, on the other, animal research workers. As a practical outcome of the deliberations, a number of specific lines of work which call for immediate investigation are suggested, together with outlines of the type of experiment which could be usefully conducted on a long-term basis.

Fall in World Malaria

WHEN the effectiveness of DDT against mosquitoes was realized, and particularly when the value of residual films of this insecticide was discovered, hopes were raised that at last a method had been found which would make possible the control of rural malaria at a practicable cost. A recent article by E. J. Pampana (*Bull. Org. Mondiale de la Santé*, 3, 557; 1951), written at the suggestion of the Executive Board of the World Health Organization, summarizes the results of a number of large-scale campaigns in Africa, America, Asia and Europe in which the use of residual insecticides figured prominently. It makes encouraging reading. In treated regions of Brazil, notified cases of malaria fell from 18,297 in 1945 to 976 in 1949; in one typical village in British Guiana, the spleen index fell from 71·6 per cent in 1945 to 4 per cent in 1948; in Ceylon, infant mortality in 1949 was only 62 per cent of what it was in 1946; in Greece, the most malarious country in Europe, where morbidity varied from 1 to 2 millions a year between 1930 and 1940, malaria has now "ceased to constitute a serious public health problem". A conspicuous gap in the reports is left by tropical Africa where, as yet, very little seems to have been done. Two problems loom ahead: a possible breakdown in the method if the mosquito becomes tolerant to the insecticide, and a great upswing in human populations if these measures continue to prosper.

Antihistaminic Agents in Allergy

A VALUABLE publication, "Antihistaminic Agents in Allergy" (*Ann. New York Acad. Sci.*, 50, Art. 9, 1013; 1950; 3 dollars) records the papers given at a conference on this subject held in October 1947. Although about half the papers deal with antihistaminic agents, the remainder deal with histamine itself; and among these a paper by Sir Henry Dale, entitled "The Pharmacology of Histamine", includes a brief survey of evidence for the occurrence of histamine and its liberation and participation in natural reactions. The volume as a whole records the results of a great deal of research, and the bibliographies appended to each paper indicate how extensive the study of histamine and antihistaminic agents has been.

A Royal Head from Ancient Egypt

THE Freer Gallery of Art, which forms part of the Smithsonian Institution, Washington, D.C., possesses an interesting royal Egyptian head, and the late Dr. George Steindorff was asked to describe it. His findings have been published by the Gallery in a little booklet, under the title of "A Royal Head from Ancient Egypt", which runs to thirty pages of text and twenty-nine full-page illustrations and is a commendable little study (Occasional Papers, 1, No. 5; Pub. 4022; 1951). Dr. Steindorff has taken the opportunity not only to make a study of the particular sculpture in question, but also to illustrate for purposes of comparison the various styles in sculpture that appear at different times in Egyptian history. The result is a very useful little brochure for those interested in portrait sculpture who do not happen to be specialists in Egyptian archæology.

Ancient Polynesians as Navigators

AN article by T. G. F. Mann (*Irish Astro. J.*, 1, No. 4; 1950), with the title "The Polynesian, Master Mariner and Astronomer", outlines the extraordinary navigational ability of the early Polynesians in their voyages through the central and eastern Pacific, the islands of which are peopled by a race which displays very remarkable similarities in appearance, character, language and traditions. It appears that they used the stars as compass, chart and chronometer, and the Pleiades and Antares were especially utilized. It is remarkable that they fixed the northern solstice about June 25, and this was determined by the appearance of the Pleiades at about 5 a.m. 22° above the horizon. A description of their method for determining degrees is given and, crude as it may seem, it was sufficiently accurate to enable the navigators to find their directions for thousands of miles across unknown seas. It is believed that the people in the Hawaiian group were able to measure the altitude of Polaris by means of a gourd filled with water. It is very remarkable, as the author points out, that when the Western mariner was largely confined to the Mediterranean, creeping cautiously along its seaboard, the Polynesians regularly covered thousands of miles of open sea.

Properties and Uses of Photoelectric Cells

AN illustrated booklet, "Electric Eyes", by A. J. Fawcett and published by the Tintometer, Ltd., Salisbury, contains an elementary and somewhat entertaining account, suitable for the non-technical reader, of the properties, use, advantages and disadvantages of the photoelectric cell. Part 1 deals with the use of the photoelectric cell on the underground railways where the interruption of a beam of light by the train sets the signals; as a burglar alarm, a counting or safety device; to grade manufactured articles according as they are light or dark; for smoke detection and to measure the turbidity or pollution in canals and rivers. Part 2 is concerned with colorimetry. It is emphasized that the photoelectric cell is colour-blind and that it is a robot device. "Its failures in the field of colorimetry are not the shortcomings of the photoelectric cell, but of the operator who is making unreasonable demands upon it." The constructions of the photoemissive and the barrier-layer or photovoltaic cells are described in an appendix, the way in which the latter type of cell works being illustrated pictorially by rabbits in a field near their burrows. For the benefit of those on unfamiliar ground, the booklet is completed by a glossary of terms used.

Municipal Library System of London and the Home Counties

The sixth report of a quinquennial series issued by the Library Association (London and Home Counties Branch) summarizes information regarding the rate-supported municipal library system of London and the Home Counties as existing on March 31, 1949 (pp. 32; general editor, James D. Stewart; London: Central Public Library of Hampstead, 1951). The report covers 119 separate library authorities in the counties of London, Bedford, Berkshire, Buckinghamshire, Essex, Hertford, Kent, Middlesex, Surrey and Sussex, and the information analysed includes all grades of the public library service. The development of the library service in the area over a quarter of a century is traced, and the report is essentially factual: conclusions as to the value and tendencies of details of policy are sparingly drawn. Generally, the service of the area reaches twice as many people as in 1924; issues of books are more than four and a quarter times more numerous; its stock of books has increased more than fourfold; and there are nearly five times as many registered readers as in 1924.

Certificates and Diplomas in Management Studies

The British Institute of Management was established in September 1947 and, early in 1949, undertook to administer jointly with the Ministry of Education a national scheme of management studies, the Institute acting as the co-ordinating authority for the various professional bodies concerned. Regulations covering the national scheme agreed to jointly by the Ministry and the British Institute of Management, and the Scottish Education Department and the British Institute of Management, were published in 1949 and 1950 and, since that time, technical colleges have been changing over to the new scheme. The majority of professional management bodies agreed to accept a common intermediate certificate in place of their own examinations, while the professional technical institutions which include management studies in their requirements are prepared to grant certain exemptions. Now it may be said that the intermediate certificate stage has been successfully launched, and the second stage, the preparation of suitable diplomas for various specialized management organizations, is under consideration. To clarify the present position and to collate existing information, the British Institute of Management has prepared a handbook giving full details of the examinations, a list of institutions accepting the common intermediate examination, and the proposals for the development of diplomas in management studies. The handbook may be obtained from the British Institute of Management, Management House, 8 Hill Street, London, W.1, price 6*s*. 3*d*.

Announcements

Dr. C. W. Allen, of the Commonwealth Observatory, Mount Stromlo, Canberra, has been appointed to the Perren chair of astronomy tenable at University College, London, from October 1, or as soon thereafter as possible.

Prof. J. Brontë Gatenby, professor of zoology and comparative anatomy in Trinity College, Dublin, has been appointed visiting professor of zoology in the Faculty of Science, King Farouk University, Alexandria, from October 1.

The Exhibition on the "Human Factor in Industry", at the Safety, Health and Welfare Museum, Horseferry Road, Westminster, London, S.W.1 (admission free; 10 a.m.–6 p.m.), which was to have closed on September 29, will remain open until October 19.

Sir George Beilby Memorial Fund awards, which are considered by administrators representing the Royal Institute of Chemistry, the Society of Chemical Industry and the Institute of Metals, are made at intervals to British scientific research workers, preference being given to investigations relating to the special interests of Sir George Beilby, including problems connected with fuel economy, chemical engineering and metallurgy. In general, the awards are granted to younger men and women for original work done over a period of years. Awards may be made early next year, and the administrators request that their attention be directed to outstanding work of the nature indicated, not later than December 31. All communications should be addressed to the Convener of the Administrators, Sir George Beilby Memorial Fund, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

The eighteenth Christmas Chemical Engineering Symposium, arranged by the Division of Industrial and Engineering Chemistry of the American Chemical Society, will be on the subject of "Nucleation" and will be held at Northwestern University, Chicago, during December 27–28. The programme will be divided into the following four sections: theoretical aspects, and nucleation from the gas, liquid and solid phase respectively. Attendance is open to all; but papers must be sponsored by a member of the American Chemical Society. Communications should be addressed to the chairman of the Papers Committee, C. M. Cooper, Engineering Research Laboratory, Du Pont Experimental Station, Wilmington, Del. Local arrangements are in the hands of Dr. L. F. Stutzman, of Northwestern University, Evanston, Chicago, Ill.

Erratum. In the article entitled "The Development of Taxonomic Theory since 1851" by J. S. L. Gilmour in *Nature* of September 8, on p. 402, column 1, a line of type following line 16 has been omitted. The sentence should read: "It can be called phylogenetic only in a secondary sense, namely, that the reason why a particularly natural biological classification can be made at all is the paramount influence of heredity on the characters of living things. . . ."

INTERNATIONAL UNION OF CRYSTALLOGRAPHY

CONGRESS AT STOCKHOLM

THE Second Congress of the International Union of Crystallography, which was held at the University of Stockholm during June 27–July 5, was attended by more than three hundred members from different parts of the world. Although Britain and the United States provided the largest foreign contingents, the diversity of other nationalities was such that the English-speaking people were in the minority; nevertheless, English was used as the main medium of communication, although some papers were given in French and German. Tribute must be paid to those who forsook their native language to speak English, and to others who, having no English, took particular pains to make themselves clear; unfortunately, the speed of delivery of some of the English papers must have made it difficult for them to receive much in return.

As in the first Congress (see *Nature*, 162, 838; 1948) so many papers were presented that it was found necessary to hold simultaneous sessions, this time in triplicate. Thus it was impossible for a single observer to hear all the papers, and the present account must be regarded as representing mainly the particular interests of the writer; it is mainly concerned with X-ray diffraction, and for the section on electron diffraction he is largely indebted to Dr. L. E. Sutton, of Oxford, who kindly allowed access to some of his notes.

Instruments for X-ray diffraction. It is interesting to compare the state of the subject of X-ray diffraction with that existing at the time of the first conference, in 1948. There would seem to have been a period of stabilization, as no discoveries of major importance have arisen; but we can now see much more clearly how some of those made just after the War fit into the general scheme.

For example, consider instruments. In 1948, we were only beginning to see the application of Geiger–Müller counters to single-crystal work, although their use for powder work had been fairly thorough. We can now see extremely important developments. The results are more accurate than those obtained photographically, but only if a great deal of trouble is taken in obtaining them. Consequently, at present, the method would be employed only if extreme accuracy is required, and it is likely that, for most structure investigations, photographic equipment will continue to be used. There is, however, no reason why improvements in instrumentation should not change this state of affairs, and we may find that ultimately photographic methods will be relegated to quite a minor part in structure determination.

Neutron diffraction is also developing rapidly; with the introduction of the neutron spectrometer at Harwell, practical work is no longer confined to America. For obvious reasons, it is unlikely that neutron spectrometers will ever become very numerous, and hence it is important to see that they are used for those problems for which they are particularly suitable. We cannot, therefore, expect that they will make great contributions to orthodox crystal-structure studies, but nevertheless they are opening up a new field of their own. A particularly fascinating subject is that of the antiferromagnetics, in which neutrons are able to differentiate between isotopes of which the magnetic moments are opposed; superlattice effects are found which are quite undetectable by X-rays.

Crystal-structure determination. Methods of crystal-structure determination figured largely in the Congress, and were the subject of a detailed symposium held after the Congress had ended. Many interesting new ideas were described; but none could be considered as likely to revolutionize the subject. They are more likely to simplify the determination of structures of which the unit cells contain relatively few atoms, but of which the chemistry is uncertain; for structures with large numbers of parameters, the well-established methods which make use of isomorphous replacement and heavy atoms still stand supreme.

The new methods attempt to make use of certain general properties that crystals must possess—that is, that they are composed of atoms of known electron densities. The Harker–Kasper inequalities, for example, make use of the fact that electron densities are always positive. Attempts are now being made to make use of the known interatomic distances, and some success has been obtained with the resulting methods on crystals that have one small cell dimension. Attempts to make use of other facts—for example, that the electron density must be zero at a centre of symmetry if all the atoms are in general positions—do not seem to be fruitful.

Considerable help to the application of these methods has been given by the Fourier machine at Pennsylvania State College. This machine, which produces two-dimensional electron-density maps almost instantaneously, was not yet finished in 1948; but reports now show that it fully justifies the claims made for it. Not only is it helpful in greatly speeding up routine work, but it also seems to be inspiring the application of some of the theoretical methods mentioned in the previous paragraph.

The 'steepest descents' method has not proved to be capable of deriving structures *ab initio*, as was hoped on its first introduction, and it now appears to be settling down as a method for the refinement of approximate structures. Other methods, such as 'least squares' and the 'difference synthesis', also exist for this process, and there would seem to have been distinct advances both in the accuracy and the assessment of accuracy of structure determination in the past three years.

Perhaps the greatest advances in crystal-structure determination, however, are taking place in the application of the Patterson synthesis; this method, which is now fifteen years old, still seems to be capable of providing fresh approaches, and closely similar lines are being followed in France, Spain, the United States and Great Britain. It will be interesting to see, at the next Congress, whether these approaches will prove to be as fruitful as their supporters claim.

Electron diffraction. Considerable technical progress was described in dealing with the diffraction of electrons by gases. The main difficulty in this subject is the extreme variation of the intensity of scattering with angle; if the lower part of the pattern is adequately exposed, the higher parts, which govern the accuracy of the conclusions, cannot be observed.

The main method of overcoming this difficulty is to place a rotating sector over the film during the exposure, so that the observed intensity is reduced according to a known function of scattering angle. With such methods it is possible to observe diffraction patterns down to spacings of about 1·5 A., and thence to derive interatomic distances to an accuracy of about 0·01 A. Many examples of the application of this method were described by workers from Norway, Japan, the United States and Great Britain.

Some extremely interesting photographs of diffraction effects from single crystals were also shown. The possibilities of using electron-diffraction photographs in crystal-structure determination had been pointed out in 1939; but no great progress seems to have been made in this subject. Possibly, considerable difficulties are involved in eliminating the secondary diffraction effects, such as Kikuchi lines, which are given by perfect crystals; but if these could be eliminated or allowed for, the electron-diffraction method might prove to be an extremely useful tool.

To summarize, it may be said that the field covered by the diffraction of X-rays and electrons continues both to expand and to knit itself more closely together. An increasing range of materials has come within the scope of the methods, and connexions are being found between the different methods and techniques that are used. Relationships have been discovered between what were thought to be isolated subjects, and the degree of strength given to these methods of studying matter augurs well for future advances.

H. Lipson

CHEMICAL INDUSTRY IN GREAT BRITAIN

The discussion on August 10 on "The Changing Face of Chemical Industry" before Section B (Chemistry) at the British Association meeting at Edinburgh was opened by Mr. J. Davidson Pratt. As general manager of the Association of British Chemical Manufacturers, it was natural that Mr. Pratt should make some reference to the report on the British chemical industry which the Association prepared two years ago. That report fully displayed not only the scientific character of chemical industry but also its essentially dynamic nature; and beyond quoting the figures given in that report for the industry's estimated expenditure on research to illustrate his point that for chemical industry research is a necessity—and a costly one—Mr. Pratt did not attempt to recapitulate. He made a second point regarding the number of small units still operating, and that success here demands the same qualities of individuality and initiative which have in the past century been responsible for so many remarkable developments and the rise of many of the best-known firms in the industry.

The complexities of both the scientific and technical sides of the industry were indicated in the paper by Dr. F. Roffey on petroleum chemicals, and in that by Dr. J. C. Swallow on synthetic polymers. Dr. Roffey pointed out that, in very general terms, the petroleum chemical industry, which derives its raw material from petroleum or natural gas, has its main influence on the large-scale production of aliphatic rather than aromatic products. In this it is complementary to the older coal-tar industry, although highly important developments have been based on the use of intermediates derived from both. Since the middle 'twenties, the growth of the industry has been remarkable. Dr. Roffey indicated some of the developments and inter-relations on the chemical side, which, as distinct from the breakdown of any given feed-stock into its component hydrocarbons or closely related groups of hydrocarbons—essentially the responsibility of the oil industry—is the task of the petroleum chemical industry.

Dr. Roffey's review of some of these products which are provided for the field of synthetic plastics, fibres and rubbers linked naturally with Dr. Swallow's review, which aimed at giving a picture both of the overlapping relations of these three types of synthetic polymer and of the possibilities of synthesizing a polymer with the properties required for a specific application. There are, however, limiting factors which prevent the production of these new materials in sufficient quantity for all our needs. The lag of seven to ten years between discovery in the laboratory and successful industrial production has still to be faced, and there have been further economic difficulties since the War. Some of these were indicated in the report on chemical industry, and the orderly introduction of new materials into modern economy represents one of the more difficult tasks facing chemical industry, and the industries which use these products for obtaining new technical effects.

In general, the symposium had an economic or even sociological trend that would have made it almost equally appropriate to Section F. What Mr. Davidson Pratt had observed about concentration on quality and efficiency rather than on quantity and output, as in the earlier chemical industry, appeared to be supported by both the following papers. The economic and social background of the industry was even more prominent in a most interesting paper contributed to the symposium, namely, that in which Mr. H. W. Cremer, following the chairman's opening remarks, dealt with some general considerations, mainly from the point of view of the chemical engineer; but he also directed attention to the need for an informed and alert public opinion to prevent some of the undesirable features of the early development of chemical industry, such as atmospheric and water pollution. He insisted frankly that failure of the general public to make active protest was at least partly responsible for such defects.

Mr. Cremer pointed to a number of factors which are giving rise to a different outlook and to better conditions both inside and outside the industry. The increasing competition from industrially minded countries, by necessitating higher process efficiencies, has in consequence diminished waste of materials in effluents and in atmospheric pollution. Stringency of supplies of raw material, including water, can operate in the same way, while the extension of the industry to include a much wider range of products such as textiles, foods and pharmaceutical preparations, requiring manufacturing techniques of a very different character from those employed in the so-called 'heavy' chemical industry, is giving organic chemical industry the character of a fine-chemical industry. Developments in insecticides and in fertilizers have aligned chemical industry closely with agriculture, and he regarded the prospect opened up by the utilization of plastics as almost limitless. He attached much importance to the disappearance of the old differentiation between pure and applied science, and to the unification of outlook to be seen in the approach to problems in modern chemical industry. This finds expression in the team-work in which mathematicians, physicists, chemists, biologists, geologists and metallurgists may all participate, and Mr. Cremer thought that, in thus furthering the idea of the unity of science, that co-operation and interchange between universities and industry which is so essential and fruitful may also be stimulated.

Other factors changing the face of chemical industry to which Mr. Cremer referred were the introduction of new constructional materials, with all their implications for the design of plant to operate under more and more exacting conditions of pressure or temperature, the remarkable developments in scientific instruments which are not only increasing the accuracy of control but also making it possible for such control to be automatic or remote, and the contribution of the chemical engineer in the study of selected categories of process operations, based on the same physical principles although their method of application may differ with the properties of the individual product to be manufactured. Besides this, the attention now being given to the safety and welfare of the workers in chemical industry is also affecting its character as well as the design of its plant. The study of occupational diseases has sometimes stimulated research on disease in wider fields, and the industry in its work on toxicology and like matters is concerned with the health and safety of users of its products as well as of those making them. Mr. Cremer believed that the industry is now fully conscious of all its direct and indirect obligations to the public, and that there is now much better prospect of science being properly wedded to industry and, in turn, of industry to civilization.

But it seems equally clear from this symposium that the future of chemical industry will not depend solely on internal factors, but also on whether Government policy and the general social or political climate are favourable. There was implicit concern that fiscal policy may place fresh difficulties in the way of development when obsolescence is so large a consideration and research and development so costly, and whether there will continue to be forthcoming the initiative and individuality, the enterprise and imagination which are required to create and to seize these opportunities.

STUDENT HEALTH IN GREAT BRITAIN

INTRODUCING a symposium on student health before a crowded session at Edinburgh of Section I (Physiology) of the British Association, Sir Andrew Davidson, chief medical officer, Department of Health for Scotland, claimed that no better nor more appropriate recognition of the importance of student health has been recorded than its inclusion in the discussions this year of the British Association. We have been guilty hitherto of neglecting an important group of the community from which not only our men of science but also other leaders of the nation are most likely to come.

Eighty-five thousand full-time students attend universities and colleges under the ægis of the University Grants Committee, and probably as many more attend other central institutions for higher education. In Scotland there are about thirty-one thousand students in all. This very substantial occupational group is subjected to stresses and strains —both physical and mental—which demand special understanding.

The promotion of full health and the prevention of ill-health, with measures for the early diagnosis and treatment of disease, should be the aim of all student health services. Curative medicine must have its place but should, wherever possible, be arranged within the National Health Service. The best features of our school health services and our industrial health service should be incorporated—the personal health programme and the health education work of the former, and the environmental effort of the latter. The approach to student health work should be through physiology rather than pathology.

Stressing the importance of health education, Sir Andrew quoted the Goodenough Committee Report. "A student health service would be one of the means of inspiring the community to a sensible interest in the promotion of health. . . . the service would be a special education for them [students] as providing a practical demonstration of medical practitioners in the role of health officers. Such a demonstration related to a student's own health and problems is likely to make a much more lasting impression than much exhortation."

Of particular interest were Sir Andrew's remarks on research in student health services. In no other section of the community do such excellent opportunities exist for research in health. The combination of an intelligent, young, apparently healthy person and a doctor with reasonably adequate time is unique. There is, too, an almost unexplored field of investigation of a group living through one of life's most critical stages. Inquiries into environmental, social and personal factors, physical exercise, nutrition and so forth can provide invaluable information, which may perhaps indicate routes of development in our health services. There is the added advantage that the student can be closely observed for three to five years, while his later history may even be followed up for a longer period. Where can intelligent co-operation be more readily forthcoming, asked Sir Andrew ?

During the limited time available for eye testing in the medical examination of large numbers of students, anything more elaborate than the monocular Snellen test is usually considered to be impossible. This test, however, fails to reveal many instances of binocular defects, anisometropia suppression, and so on. Dr. R. H. Bolton, of the University of Birmingham, described in an impressively lucid paper how he has adapted the Turville infinity balance to provide a 'screening' test, which, though not yet completely infallible, nevertheless provides a simple test markedly superior to any other screening test in his experience. The Turville infinity balance is essentially an extension of the well-known binocular reading test in which a pencil or narrow strip of paper is held between the eyes and the test type. The pencil is replaced by a sand-blasted septum in the centre of a mirror in which back-to-front letters are reflected and read, different letters being read by each eye. This "gives a satisfactory indication of how the student is using his eyes as a pair and saves a lot of time". By applying a surface-silvered mirror immediately behind a clear-glass septum, but slightly out of alignment, a virtual image of the test letters is seen binocularly immediately above the separated or monocularly seen types, providing a standard for detecting even minor degrees of 'phoria' or faulty alignment. At a second testing 'station' each student undergoes a colour vision test, a binocular reading test, and near-point phoria test using a Maddox convergeometer. From the subsequent histories of those examined by him, Dr. Bolton confirms the usual view that 'esophores' are more likely to have eye troubles than 'exophores' or 'orthophores'.

As part of a wider study of the socio-medical and environmental background of 2,539 students of all faculties at the University of Edinburgh, Dr. J. G. Thomson has considered the association of these factors with the academic results achieved by 592 medical students from all years except the first, and by a second group of 137 first-year medical students.

Three-quarters of all students and 83 per cent of medicals were from social classes I and II (the upper social classes). Family size does not show the normal variation between the social classes, and students from lower classes obtain academic results as good as those from other classes.

Students entering the medical faculty at ages between twenty-six and thirty showed the best academic results, followed by those who started at less than eighteen years of age. Of the year-group 18–25, those entering between the ages of twenty and twenty-two gave the poorest results of all. There was no evidence in this group that national servicemen did better or worse than non-servicemen, and, of the physical and environmental factors considered, only myopia showed a slight suggestive association with superior academic performance.

In the first-year group, students living at home did less well than those in lodgings approved by the university welfare superintendent. Room-sharing, longer hours of daily travel-time, and differences in recreational habits did not account for this, and the solution was found in a group of twenty-three students from English secondary schools who were very much more successful than any other group. What appeared to be an interesting environmental difference was, therefore, probably the result of pre-university educational factors, or of varying selection criteria.

Presenting a provocative and enjoyable paper on the relationship between physique and physical attainments, habits and behaviour, including delinquency, Dr. R. Parnell, of the University of Oxford, created a stir with a formula based on physical measurements and radiographic heart-size, which not only differentiated sprinters from long-distance runners, but also graded them according to potential performance. He confidently predicted that a particular athlete at the top of his table would win the 1,500-m. race at the Olympic Games at Helsinki next year.

A comparison of heights and weights in the University of Oxford revealed once again that students from the lower social classes are smaller than those from the other social classes. Since, however, students from government grant-aided schools are "taller and heavier than the highest level reached in the general population", Dr. Parnell argues "that the great difference between undergraduates and the general population is probably due to selection" and not to nutritional advantages. Is it not more probable that working-class parents who are ambitious for their children do, as demonstrated in Dr. Thomson's paper, limit the size of their families in order to give them both educational and nutritional advantages?

The classification of physique by methods of standard photography based on the Sheldon technique, and standardized by the work of Tanner in Great Britain and Dupertuis in the United States, has produced evidence in support of those who propound a relationship between physique and behaviour. Dr. Parnell demonstrated the use of the 'fat clock', a graphic method of recording physical measurements and the thickness of the subcutaneous fat, which will be a useful technique for all those who are interested in this work.

In a powerful plea for a deeper appreciation of the problems of the tuberculous student, Sir Alan Rook, of the University of Cambridge, estimated that there are probably close on five hundred undergraduates in sanatoria in Great Britain and more than two thousand in need of medical care or observation for pulmonary tuberculosis. After discussing the problems of adjustment and career selection which face those students who are able to continue their studies while under observation, Sir Alan went on to paint a graphic picture of the frustration, the loss of initiative and desire to work, or the fretfulness and restless anxiety of these young people, progressing all too often to a profound psychological maladjustment, which not only retards recovery but also impedes resettlement after cure.

After referring to the success of Continental students' sanatoria, which he reluctantly classed as impracticable in Great Britain at present, Sir Alan asked that, at least, we should establish something corresponding to the Continental post-cure hostels for tuberculous students.

This must not be thought of as preferential treatment any more than rehabilitation units for industrial workers and 'Remploy' factories can be considered 'preferential'. The correct treatment should be available to all, and Continental experience has shown that the correct treatment for university students includes the mental stimulus of continued teaching and study under medical supervision. It is scarcely creditable to British universities to have lagged so far behind Continental practice in this matter. Now, however, the students of Great Britain are pressing strongly for action, and have collected a large sum of money towards this project. It is to be hoped that Sir Alan's plea will bring them the influential support for which they look so hopefully.

As the speakers freely admitted, much of their work is exploratory and open to criticism or even correction. The important thing is that a start has been made. A regular stocktaking of the health, well-being and occupational efficiency of those on whom the advancement of science will depend in the future will be of great interest to members of the British Association, especially if the approach continues to be "through physiology rather than pathology".

ARMAGH OBSERVATORY

REPORT FOR 1950

THE March issue of the *Irish Astronomical Journal* (1, No. 5; 1951) contains the report on Armagh Observatory for the year 1950, in which Dr. E. M. Lindsay, the director, gives the main items of interest and development for the year. The Armagh–Dunsink–Harvard telescope is now in operation at the Boyden Station of the Harvard Observatory at Mazelspoort, Bloemfontein, where it arrived on October 26, 1950, and was erected under the supervision of Dr. J. S. Paraskevopoulos and Dr. Bok shortly before the death of the former. The primary mirror has a diameter of 36 in., the secondary mirror 16 in., and the correcting plate 32 in. The photographic plate covers an area of about 18 square degrees, and the scale is 1 mm. = 68″. An exposure print of 61 min. is reproduced and shows the excellent performance of the instrument and its efficiency in the photography of diffuse nebulæ. A member of the staff of Armagh Observatory spends four months of the year on the observational programmes on the Southern Milky Way with the telescope. The report includes a photograph of the instrument. The completion of the objective prism for the telescope is well under way; it will be 33 in. in diameter—the largest in the world—with a 5° angle giving a dispersion of about 400 A. per mm. The cost of the prism so far has been borne by Harvard University and by a grant from the Senate of Queen's University, Belfast.

Dr. E. B. Armstrong commenced erecting the Armagh Schmidt telescope in August 1950, and the final adjustments were being made and test plates taken early this year.

The remainder of the report gives a list of publications, a summary of the meteorological work, the names of a number of visitors, a miscellaneous collection of information on lectures by Dr. Armstrong at Queen's University, the synchronous motors for the meteor cameras, various internal renovations and alterations in the buildings, etc.

A NEW MEASUREMENT OF THE VELOCITY OF RADIO WAVES

By Commdr. CARL I. ASLAKSON

U.S. Coast and Geodetic Survey, Washington, D.C.

During January and February of 1951, I was privileged to assist in some new tests of improved Shoran equipment. These tests were undertaken by the United States Air Force, and in general the methods employed were those developed by me[1–4]. However, several improvements were incorporated in the equipment by the United States Air Force, the most important one being a 'gain-riding technique', whereby the gains were manually controlled and maintained, both at the ground station and in the air, at a constant level. This technique effectively eliminated the 'signal intensity' correction reported in the earlier work.

The lines measured constituted a five-sided figure with a central point. Since the distances between all points were measured, there were fifteen lines in all. These distances varied from 40 to 320 miles, as shown in Table 1.

Table 1

1	2	3	4	5	6	7	8
Line	Ground stations		Geod. distance	Shoran distance	Shoran minus geodetic	Col. 6 corrected for K	Adjusted V
	Rate	Drift					
2–6	2	3	40·6131	40·6041	−0·0090	−0·0038	+0·0008
3–4	1	3	96·7171	96·7049	−0·0122	−0·0063	+0·0024
5–6	1	2	100·3098	100·2988	−0·0110	−0·0054	−0·0007
5–1	1	3	118·9953	118·9840	−0·0113	−0·0074	+0·0002
1–6	1	2	133·0113	132·9985	−0·0128	−0·0072	−0·0009
2–3	2	3	134·9698	134·9546	−0·0152	−0·0095	+0·0013
5–2	1	2	139·1225	139·1127	−0·0098	−0·0059	−0·0025
3–6	1	2	145·8427	145·8276	−0·0151	−0·0095	+0·0006
1–2	3	2	145·8884	145·8768	−0·0116	−0·0059	−0·0029
4–6	1	2	190·5047	190·4889	−0·0158	−0·0102	−0·0013
2–4	1	2	199·1914	199·1735	−0·0179	−0·0123	+0·0002
5–3	2	3	226·9903	226·9698	−0·0205	−0·0148	+0·0010
5–4	1	2	235·5264	235·5042	−0·0222	−0·0166	+0·0023
1–3	2	3	277·0569	277·0347	−0·0222	−0·0166	−0·0003
1–4	1	2	320·1519	320·1271	−0·0248	−0·0192	−0·0002

Probable error of observation = ±0·00118

All stations were tied to the first-order triangulation network of the United States, and the inversed geodetic distances could thus be compared with the Shoran distances.

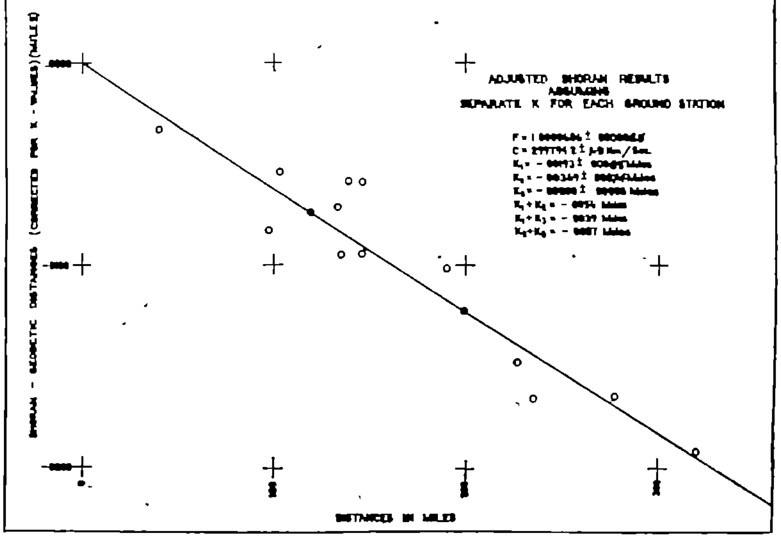
Three Shoran ground stations were used, but only a single airborne station. Each ground station is known to have a small constant error which can be determined by calibration over a known distance. This error varies from about −0·002 mile to −0·003 mile. In the present case it was possible to make an excellent analytical determination of this error from the results of the measurements.

The original Shoran measurements were made using the Anderson value of $c = 299,776$ km./sec. Therefore, that velocity must be multiplied by the factor 1·0000606 derived from the adjustment. This results in a velocity of 299,794·2 ± 1·9 km./sec.

The solution was made from fifteen observation equations, one for each line measured. The equations were as follows:

$$FS + K_1 + K_2 - E = 0.$$

Column 6 in Table 1 gives the value of E in each equation. Column 7 contains these values of E after correction for the computed ground station values of K, while column 8 shows the V's or the corrections to the distances. The other terms in the equation are defined as follows:



F is the scale factor representing the velocity change from the assumed velocity. The values K_1, K_2, and K_3 are the constant errors in measurement, which are a function of the individual ground stations, and E is the Shoran distance minus the geodetic distance.

The results of the above solution are:

$$\begin{aligned} F &= 1\cdot0000606 \pm 0\cdot0000065 \\ \text{or } c &= 299{,}794\cdot2 \quad \pm 1\cdot9 \text{ km./sec.} \\ K_1 &= -0\cdot00193 \quad \pm 0\cdot00065 \\ K_2 &= -0\cdot00369 \quad \pm 0\cdot00074 \\ K_3 &= -0\cdot00200 \quad \pm 0\cdot00053 \end{aligned}$$

The Shoran distance was S.

$$\begin{aligned} \text{Thus} \qquad K_1 + K_2 &= -0\cdot0056 \\ K_1 + K_3 &= -0\cdot0039 \\ \text{and} \qquad K_2 + K_3 &= -0\cdot0057 \end{aligned}$$

The probable errors in these values of K are sufficiently low to indicate that the analytical method of determination is satisfactory.

These results are summarized in the accompanying graph, which shows the adjusted velocity curve together with the individual observations. The derived velocity of 299,794·2 ± 1·9 km./sec. is higher than the one previously reported by me. However, the removal of the troublesome signal intensity error together with other improvements in the equipment and the techniques lend more confidence to the above figure.

In my previously reported value[3] of c, a value of the index of refraction for dry air at 760 mm. pressure and 0° C. of 1·0002835 was used. In the present work I have adopted a value of 1·0002876. That figure is based on the means of a number of measurements made by various observers in the optical band. Warner[4] adopted a statistical value of 1·0002895 ± 0·0000550, basing that figure on the dielectric constant determinations of seventeen workers between 1872 and 1946. Birnbaum, Kryder and Lyons[5] published a value of 1·0002853 for air and 1·0002877 for air as determined from its component gases. Essen[6] recently published a value of 1·0002882. In the same paper Essen states that a new optical equation of Barrel gives a value of 1·0002878. It seems certain that the figure I have adopted is accurate to about 1 part in 10^6.

Essen[7] summarizes recent determinations of the velocity of light. In Table 2 I have added my value to his list.

Table 2

Author	Method	Velocity *in vacuo*	Weight
Birge	Optical	299,776 ± 4 km./sec.	1
Essen and Gordon-Smith	Cavity resonator	299,792 ± 9	1
Bergstrand	Optical	299,793·1 ± 0·26	2
Aslakson	Radar	299,792 ± 2·4	2
Essen	Cavity resonator	299,792·8 ± 3	2
Bol	Cavity resonator	299,789·3 ± 0 4	2
Aslakson	Radar (Shoran)	299,794 2 ± 1·9	

It is particularly noteworthy that these observers used widely varying frequencies, ranging from the optical wave-lengths of Bergstrand, through the 220–300 Mc./sec. of the Shoran band to the 30 Mc./sec. of Essen's experiments.

Aslakson's 1949 value would be reduced by about 2 to 3 parts in 10^6 if the new value of the index of refraction and the corresponding interpolation equation were used. Certainly the close agreement and relatively low probable errors are significant.

At the present time a new series of Shoran measurements is in progress. The value of the velocity assumed in projects now under way is 299,793·1 km./sec. So far, comparisons of measured distances and Shoran distances indicate that this value is correct within 1 part in 150,000.

A more complete report of the measurements described here will be published elsewhere.

SCIENTIFIC MANAGEMENT

IN a stimulating article, the warden of Urchfont Manor Residential College for Adult Education suggests that there is a real danger of accepting a number of false propositions in the name of so-called 'scientific management' (*J. Inst. Personnel Management*, 33, No. 315; May–June 1951). In an analysis of what is implied by the term 'scientific management', Mr. Hunter suggests, first, that there are parts of management in which certain sciences are of use. Good statistical analysis of costs, accurate measurement, controlled experiment on alternative methods of layout or process will clearly be useful and are rightly called 'scientific'. Motion study also might be included, since the human body is in one sense a machine which will function best with certain directions of movement and load. When time study and rate fixing are included among the sciences, a little more doubt creeps in; owing to individual variation in rates of learning and final speeds attained, a subjective element is introduced. Aptitude testing suffers from similar limitations, for the world is full of adaptations successfully made by people with apparently crippling disability.

Secondly, although organization is often included in 'scientific management'—industry is fond of organizational charts and maxims regarding 'the span of control'—it is doubtful whether organization is in any real sense a scientific subject. There is, indeed, a considerable amount of experience regarding organization of, say, a company with many local branches or a flow production plant, but it is scarcely suitable to describe knowledge of this experience as scientific: it is mainly empirical.

It is when the term 'scientific management' is applied to the management of human beings, however, that real muddle begins. The object of management in this field is to get a large number of human beings working together in mutual co-operation and giving maximum output. If there is a science of this activity, it implies that there should be an ordered body of knowledge relating to it and capable of being applied by any competent student. The claim appears to have been made that there are laws of group behaviour which can be ascertained and used in the management of groups. If this were true, it would clearly be of immense importance to industry, since a systematic application of these laws for defined purposes should result in producing co-operative effort. Examining the nature of this claim more closely, Hunter considers the simple and semi-technical factors such as fatigue, boredom, lighting, rest pauses and hours of work. From this it might appear that a simple or at least a direct correlation between variations of these conditions and output might be established. But at once the Hawthorne experiment springs to mind, apparently proving that the effect of such variations, if any, can be completely masked by the simple fact that the working group was stimulated to higher effort by the evidence of management interest in their work.

The first difficulty in producing a science of management is that the material to be handled insists on taking a hand in the experiment. Moreover, there is little evidence that this reaction will itself be regular, or predictable. The shop steward may be flattered or co-operative, or he may decide that the whole experiment is designed to save man-power and will endanger his job.

Hunter then goes on to consider the nature of the knowledge which the psychological scientists in industry bring back to the manager who employs them.

The psychologists discover that healthy rivalry can increase production, and advise the introduction of merit rating and merit awards. Perhaps this succeeds; but perhaps it does not, and instead produces jealousy and suspicions of favouritism, in which case another scientific investigation will produce a new diagnosis—that there is too much competition and jealousy due to merit rating. They discover that fear plays an enormously important part in determining behaviour; that a suppressed fear may have results not apparently connected with its cause; for example, a man in fear of unemployment may suddenly be rude to the foreman. They discover that men have a sense of dignity and will react unfavourably if this is affronted, that praise and blame work better than indifference, and that natural leaders appear in small groups and may lead in good or bad directions. Experience of individual psychology should warn us that the method of detailed analysis of unique cases cannot possibly produce a system of scientific rules applicable to industrial groups. Each group is, to begin with, a collection of unique individuals; each group will be coloured by its own unique history, that of the factory or its social environment; each will be affected differently at different times by current social and political attitudes absorbed from the general atmosphere of society. Possibly a year's work by an experienced team of investigators might unravel a great deal of the psychology of a group in the machine shop, and describe it in a book of considerable length. Industrial management, however, cannot possibly work at this rate.

The manager's job in industry, as that of the military commander, is to get co-operation from a group as a result of hundreds of different personal motives and influences of history and tradition which analysis might discover among any single group. Moreover, he must succeed not only with the machine shop but also with the typists and with the whole factory, composed of many utterly different groupings. Analysis cannot give him these answers. The history and experience of human leadership will, however, tell him what qualities he must show to obtain the same good result from widely different groups.

Hunter believes that the search for 'scientific management' is a search for the lazy man's way of doing the job, for a book of rules which any manager can use. If there is such a book it is one which tells of the personal qualities which the manager must show; of the self-discipline, the imagination, and the love which he has somehow to create, very painfully, in himself in order to lead others.

In conclusion, Hunter insists that he does not want to abandon observation of industrial situations or to cease experiment on organization. The excellent work which has been done on methods of selecting foremen or of drafting joint production council constitutions, the analysis of absenteeism or the organizational chart—all these have been of high value, since they provide a better channel through which leadership can flow. But he also insists that they will never provide a science of management, because there is no such thing.

T. H. HAWKINS

FOREST POLICY IN AFRICA

UNDER the question of policy and legislature in the annual report of the Forest Department of Uganda for the year ending December 31, 1949*, the following appears: "African Local Governments are being encouraged to play an increasingly more active part in forestry work, especially in areas which have been declared to possess adequate forest estates or which are within appreciable distance of attaining that objective. As time goes on District Forest Officers will act less and less in an executive capacity in so far as local reserves, Crown Land, and the supervision of local Government Staff are concerned, and more and more in a true advisory capacity."

Such a statement is all right on paper, but its practical implications must be considered. Forestry is rather different from other branches of administration in that policies must be thought out for centuries ahead; merely changing, for political reasons, an administration from British to African in no way alters the true relation of the forest to the countryside or to the local economy. The only way to preserve forests and to improve and restore those which have been badly exploited is to place them under the *direct* administration of a staff trained in forest methods from the highest ranks to the lowest; and they must know their job and be granted annually adequate funds to carry it out. For forest work entails adequate and constant supervision from the time of obtaining the new young crop of trees until the day they come to maturity—50, 100, 150, 200 or even more years later—as is being practised in France under modern conditions. Rotations may and will be shorter in the tropics. But more rapid growth entails closer supervision and in many cases a larger staff.

From the beginning of this century some of the Colonial administrations have given in the annual forest reports statements of their forest policies; but it has been little more than words. The matter now becomes more serious. If the Africans are to enjoy in future more executive authority in charge of forests, it becomes essential that the proposed position of the trained forester, and what his authority within the forest consists of, should be closely and clearly defined. Otherwise the deterioration of the African forest estate is certain.

EVALUATION OF DISINFECTANTS

AT the British Pharmaceutical Conference, held at Harrogate during September 10–14, the chairman, Prof. H. Berry, in his address entitled "A Review of Disinfectants and Disinfection", emphasized the importance of disinfection both to the public health and to pharmaceutical practice. This subject, he said, is studied in all its aspects only in schools of pharmacy, and the modern pharmacist should be qualified to give expert advice on disinfectants and to evaluate commercial claims made for them; he should be proof against "high-powered sales talk" about them. In his address, Prof. Berry discussed with refreshing vigour the question of what constitutes a good disinfectant. Controversy about evaluation of disinfectants revolves, he said, around the type of test represented by the Rideal–Walker test and its product, the so-called phenol-coefficient. This biological test is still misunderstood and is often "misused in advertisements to gull the uninformed layman", but it has turned useless disinfectants off the market. Prof. Berry discussed its defects and explained why he considers that it is a badly designed test which "cannot by any stretch of the imagination be translated into terms of therapeutic activity or practical applicability or utility". Some disinfectants, such as 'Lysol', cetrimide and acriflavine, do not need a biological test, they can be, and are, controlled by chemical or physico-chemical specifications, such as those that are given in the British Pharmacopœia and its Codex.

The real problem, however, is the evaluation of the utility of a disinfectant after it has been standardized. For this the results of many diverse tests are required, and Prof. Berry discussed these. In Great Britain there is no official body which will adjudicate on new disinfectants, nor is the existing legislation for the control of claims made for them effective, although many of the British Dominions and the United States have attempted their legislative control. Prof. Berry commended, however, the Medical Research Council's valuable Memoir No. 11, entitled "The Control of Cross-Infection in Hospitals" (revised edition; pp. 49; London: H.M. Stationery Office, 1951; 1*s*. 9*d*. net), which gives in its Appendix A advice to hospitals on the disinfectants to be used for various purposes; he expressed the hope that the Ministry of Health will adopt a similar method of dealing with disinfectants on the open market.

The remainder of Prof. Berry's address was devoted to a useful discussion of the valuable properties, and also the limitations, of the quaternary ammonium compounds, which are challenging, in certain fields of use, some of the established disinfectants. The address concluded with a brief, but interesting, account of the discovery that some substances which were believed to kill micro-organisms quickly do not, in fact, kill them, but merely inhibit them, so that they can be revived by treatment with 'revivors', among which are ammonium sulphide and certain thiol compounds. Substances have been found which will revive organisms treated with iodine, hypochlorites and formaldehyde, but none is yet known that will revive organisms treated with phenol. Certain thiol compounds, such as glutathione, occur naturally in the body, and there is evidence that, if pathogenic organisms treated with mercury compounds are injected into the body, they may be revived and may become infective. The evaluation of disinfectants must take account of developments of this kind. Revivors can be used to find out whether disinfectants have, in fact, killed organisms.

In conclusion, Prof. Berry urged that the older disinfectants should not be lightly given up. The hypochlorites are, he said, very valuable, and he had great confidence in the phenolic preparations, 'Lysol', 'Black Fluid' and 'White Fluid', the wide non-specific action of which makes them very reliable. He made a special plea for 'Lysol', but added that the hospitals do need a non-toxic, non-irritating phenol preparation the other properties of which are not inferior to those of 'Lysol'.

CARNEGIE UNITED KINGDOM TRUST

THE thirty-seventh annual report of the Carnegie United Kingdom Trust, 1950[*], covers the completion of the Trust's first post-war quinquennium, and by the end of the year the grand total of grant payments by the Trustees had reached £4,065,555. During its thirty-seven years, the Trustees have thus been able to distribute to beneficiaries more than twice the amount of the original endowment of the Trust of £2 million, and at the same time to increase the income from the original £100,000 a year to rather more than £130,000. More than a third of the total expenditure has been on the development of library services which, as explained in last year's report, will now continue without further financial assistance from the Trustees. Nearly £250,000 has been devoted to playing-fields, mostly within the period 1926–40; but the combined effect of the Physical Training and Recreation Act of 1937 and the Education Acts of 1944 has been to place responsibility in this matter on the local education authorities. Under the same Acts, central and local authorities are now responsible for grants to village halls, to which, if all outstanding promises are taken up in full, the Trust has contributed more than £180,000.

More than £150,000 has been provided for community centres and the like, and about £110,000 on schemes of land settlement, operated by the Land Settlement Association, which, under the Agriculture Act of 1947, is now responsible to the Ministry of Agriculture. Some £450,000 has been provided for youth services and nearly £50,000 for the development of museum services, while on the Bureau of Current Affairs, now to be terminated, £123,344 has been expended. While the Bureau has not been able to establish itself as a self-supporting institution, the Trustees state that they do not regret having made the experiment to find out whether a method that had proved outstandingly successful during the War could be made economically self-supporting in time of peace. The Trustees also terminated at the end of 1950 their support of youth hostels, but the allocation to the National Federation of Young Farmers' Clubs is being spread over six years, instead of the five years originally contemplated. An individual survey on behalf of the Trust is now being undertaken by Mr. John Mack, Stevenson lecturer in citizenship in the University of Glasgow, of agencies and activities concerned with juvenile delinquency, with the object of directing attention to any gaps which might be filled by the action of either statutory or voluntary bodies in furthering existing schemes or initiating new ones.

---

[*] Carnegie United Kingdom Trust. Thirty-seventh Annual Report. Pp viii+49. (Dunfermline: Carnegie United Kingdom Trust, 1950.)

Plans for the quinquennium 1951–55 include an increase in the allocation for the development of museum services from £30,000 to £40,000, in part with the object of strengthening the administration of the Museums Association itself. For the Councils of Social Service of England, Scotland, Northern Ireland, and Wales and Monmouthshire, £27,750 has been allocated, and a sum of £30,000 for family case-work by the Family Welfare Association and Family Service Units. With allocations of £45,000 for music and drama and £5,000 for the visual arts, the total allocation for the new quinquennium is £147,750, and there is thus some three-quarters of the Trust's funds for the period still available for allocation.

RECURRENT LONG LEAVE FOR UNIVERSITY TEACHERS

THE seventeenth issue of *Communication* contains the report of the International Association of University Professors and Lecturers on recurrent long leave. By this is meant the recurrence of substantial periods of leave over and above ordinary annual vacations; the most usual arrangement is that every seventh year is recognized as a year of leave of absence from the place of normal occupation. It is well known that some universities have such schemes, while others have not. It has not been generally known precisely which universities fell into which category, nor has there been any clear knowledge as to what variations of the typical scheme there might be in universities which operate recurrent long leave schemes. A suitable questionnaire was therefore sent to fifty-eight countries where universities exist. Thirty-seven of these have replied, fifteen of them reporting that they have no regular system for long leave. These are Sweden, Finland, France, Switzerland, Belgium, the Netherlands, Austria, Hungary, Czechoslovakia, Germany, Eire, Italy, Mexico, Chile and Bolivia. This does not mean a notable lack of interest on the part of either staff or authorities. Eire (Trinity College, Dublin), for example, though having no system, does occasionally give long leave when a member of staff is invited to spend some time in another university. In the University of Brno, a professor or his associate is occasionally granted leave with full salary for study for a period of, say, three months to a year. Similarly, the University of Chile has provision for granting leave for, say, six months on full salary for study purposes—each case being considered on its merits. In Finland, the University of Abo grants leave of absence with full salary and superannuation, the recipient usually having the obligation of paying a deputy.

The other twenty-two countries have recognized systems for recurrent long leave, although in some of the countries, like Canada, Great Britain and the United States, by no means all the universities have any definitely established systems; it is in the British Commonwealth of Nations and in the United States that the practice is most firmly rooted. The list of countries in which some or all of the universities have systems for recurrent long leave is as follows: Australia, Burma, Canada, Ceylon, China, Denmark, Egypt, Greece, Iceland, India, Israel, Lebanon, Malaya (Singapore), Norway, New Zealand, Philippine Republic, South Africa, Trinidad, Turkey, United Kingdom, the United States and Yugoslavia. From the data supplied it is clear that there is a widespread desire among the universities of the world that a regular leave system should operate. Many individuals, both members of the teaching staff and administrative authorities, of several universities, have expressed their views strongly in support of the system. The general aim would appear to be a scheme on 'sabbatical' lines in the sense that approximately every seventh year should be available for leave. The majority, however, both of those who give it and of those who take it, prefer that the leave be spent usefully in study or research, while travel and rest are not excluded.

Although on paper some of the schemes appear to be satisfactory, they may not be completely realistic. In the Hebrew University of Jerusalem the scheme would appear to be working well, a high percentage of members of staff taking advantage of it. In Egypt and Ceylon advantage is taken of the opportunities offered. The New Zealand schemes which have been quite recently financed by a special grant from the Department of Education are likely to prove very attractive. On the other hand, there would appear to be a good deal of imperfection in the machinery of some of the others which considerably reduces their effectiveness.

In most cases full pay is continued during leave, although in some there is a downward adjustment. On the other hand, Egypt and Lincoln (New Zealand) add a cost-of-living bonus. Generally, the staff-strength of a department provides for leave to a teacher without the need for a substitute; but where a substitute is required, in some cases the institution provides for the payment and in others it is the individual who pays in part or in full. One of the major expenses attending leave is that of travel. Long-distance passages are covered or partially met by a grant-in-aid by about half the universities who have replied; in other cases the whole cost falls on the member. In the latter event only teachers in universities where the salaries and other emoluments are relatively good can avail themselves of the leave or attempt to undertake long-distance travel. Another difficulty which arises in some cases is that, if a man is to take his wife and family with him, it naturally adds a good deal of expenditure, whereas if he leaves them behind he has two establishments to finance. Interesting examples in this connexion are Ceylon, Egypt, Western Australia and Yugoslavia. In Ceylon a travelling allowance is made for a wife, in Egypt for both wife and children, in Western Australia a larger house allowance is made in the case of a married man on leave, and in Yugoslavia the needs of the family are arranged for by paying to them the member's salary, the member on leave receiving instead his living and travelling expenses.

In reviewing the replies to the questionnaire, the Association recommends that a system of long leave at recurrent intervals should be established in all university institutions of the world. Where such a system cannot be established, all facilities for *ad hoc* refresher or study leave should be granted. Such leave should be with full pay and superannuation and adequate travelling allowances. If it should be necessary to pay for a substitute, funds should be provided by the institution for this purpose. The leave should be devoted to research, travel, rest or any other purpose to which the academic authorities could take no reasonable objection.

Detection of Sugars by Paper Chromatography

Since the introduction by Partridge[1,2] of filter-paper chromatography for the identification of sugars, the method has been widely applied by many workers, and has often proved of great value in detecting small quantities of a carbohydrate in the presence of large amounts of other sugars. With some justification, the tacit assumption, 'one sugar, one spot', is commonly accepted. We have made some observations which seem to call for greater care in the interpretation of chromatograms, and it is for this reason that the following facts are reported, although our knowledge of the phenomena described is still far from complete.

During an investigation of the sugars present in diabetic urines, three spots were observed when paper chromatograms, developed with the upper phase of a mixture of *n*-butanol (40 per cent), ethanol (10 per cent), water (49 per cent), and ammonia (1 per cent), were sprayed with aniline hydrogen phthalate[3], benzidine[4], or *p*-anisidine hydrochloride[5]. One of these spots had an R_F value identical with that of a reference glucose spot; the R_F values of the other two were, respectively, 33 per cent and 78 per cent of that of the reference spot. The slowest-moving of these substances stained with naphthoresorcinol[6] (Fig. 1), but not with ammoniacal silver nitrate[1]; on the other hand, the middle spot was observed with the latter reagent. No appreciable amount of ninhydrin-reacting material was present in the urine. On changing the developing solvent to *n*-butanol (40 per cent), acetic acid (10 per cent) and water (50 per cent), only glucose could be observed in the urine, while in *n*-butanol saturated with water the slowest spot moved only 11 per cent of the distance of the glucose spot and there was extensive streaking.

In connexion with other work on which we were engaged, samples of the polyglucoses dextran and starch were hydrolysed with 2*N* sulphuric acid in sealed tubes for 6 hr. at 100° C. The resulting solutions were neutralized either with barium carbonate or by using the desalting technique of Consden *et al.*[7]. When each hydrolysate was analysed on a chromatogram developed with butanol–ammonia, only glucose was detected if the amount of sugar employed was about 20 μgm.; but when this quantity was increased tenfold a spot was found which, in its R_F value and in its behaviour towards the spraying reagents mentioned above, was identical with the slowest one observed in the urine samples. However, it was never obtained as strongly as in the former case. This spot was again apparent when, in a further experiment, glucose itself was submitted to the acid treatment, followed by neutralization. Moreover, when a large quantity (200–300 μgm.) of pure glucose, freshly dissolved in water, was run on a chromatogram, the same spot could just be observed if the paper was sprayed with aniline hydrogen phthalate and illuminated with ultra-violet light. In some of these experiments the presence of the 'middle spot' was noted; but, due both to its low intensity and to its close proximity to the excessively strong normal spot, it was not always possible to claim its presence with certainty.

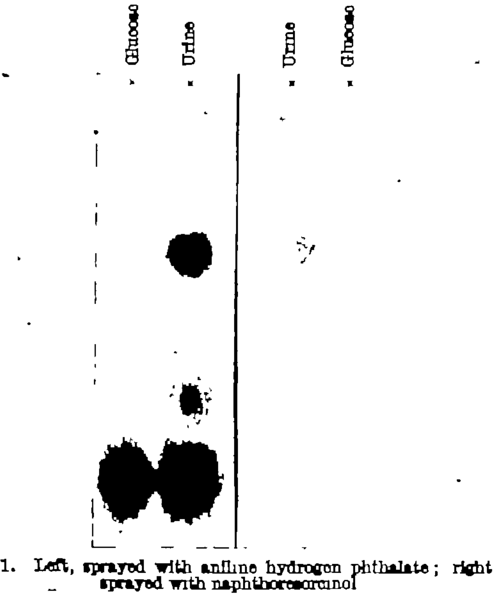

Fig. 1. Left, sprayed with aniline hydrogen phthalate; right, sprayed with naphthoresorcinol

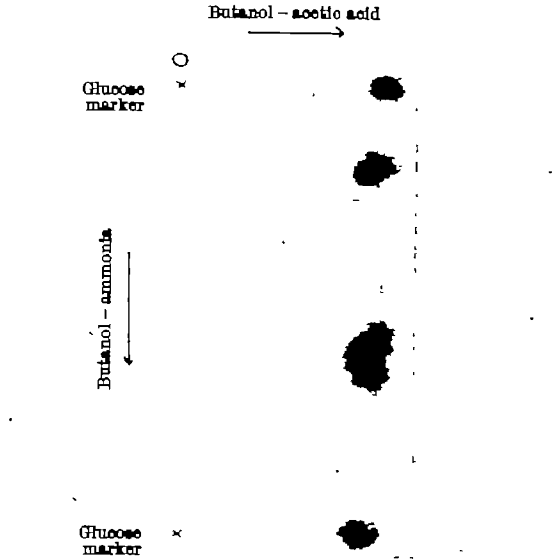

Fig. 2. Urine introduced on to the paper at position O. Chromatogram developed with (1) butanol–ammonia, (2) butanol–acetic acid, and sprayed with aniline hydrogen phthalate. Glucose markers introduced at positions × before second development

Other aldoses—both pentoses and hexoses—were found to behave similarly; but no extra spots were observed with the ketoses fructose and sorbose. The general pattern of the extra spots obtained with the aldoses was similar in all cases, and in the case of galactose the relative mobilities of the three spots were the same as in the case of glucose. However, this was not true for all the sugars examined; the slowest-moving spot obtained with ribose, for example, moved 44 per cent of the distance of the normal ribose spot. Similar phenomena have been noted with some partially methylated sugars, although the number of extra spots and their relative positions vary in a manner which appears at the moment to be almost haphazard.

When the urine sample referred to originally was run on a two-dimensional chromatogram, developed first with butanol–ammonia and then with butanol–acetic acid (Fig. 2), it appeared that all the spots reverted to glucose in the second solvent. Later, when the spot which was the least mobile in butanol–ammonia was eluted from a paper with water, using the technique introduced by Dent[7], and re-run on a chromatogram developed with the same solvent, it appeared in its original position; but if dilute acetic acid was used as the eluant the normal glucose spot was obtained on the new chromatogram. Under the same conditions the middle spot also reverted to glucose with acetic acid; likewise, the two extra spots produced from glucose by the sulphuric acid treatment were re-converted to the normal spot with acetic acid.

From the foregoing, therefore, it will be seen that we have observed on paper chromatograms phenomena which are of importance in the analysis of sugar mixtures, particularly in the examination of metabolic fluids and in the determination of the component sugars in a polysaccharide. Whether these various interconvertible spots differ in their internal structures, or whether condensation or addition reactions are involved, it is, at present, impossible to say; but the matter is being investigated further.

We are indebted to the Colonial Products Research Council for financial assistance.

Paper Partition Chromatography of Alcohols using the Potassium Xanthogenates

A FEW drops of the alcohol in a small test-tube are treated with 0·5 ml. of pure carbon disulphide and 0·1 gm. of pure powdered potassium hydroxide and the mixture shaken for some minutes. The liquid phase is decanted to another test-tube, evaporated and the residual xanthogenate dissolved in a drop of water. The resulting solution is developed by paper partition chromatography (ascending method) using alkaline butanol (2 per cent potassium hydroxide) as solvent. About twenty hours is required. The location of the xanthogenates on the paper is detected easily by their dark brown luminescence under ultraviolet light or by the yellow or blue colours produced by spraying with Grote's reagent[1]. In the case of solid alcohols, the xanthogenate formed is dissolved in formamide and developed in the same way. The R_F of formamide solutions of potassium xanthogenates, however, indicates, assuming the following reaction, the values of the corresponding ammonium xanthogenates:

$$ROCSSK + HCONH_2 + H_2O = ROCSSNH_4 + HCOOK$$

A few millilitres of ethanol, containing a trace of methanol, in a test-tube is treated with carbon disulphide and potassium hydroxide as above and is shaken for twenty seconds. After evaporation of the liquid layer, the residue of potassium xanthogenate is developed as above.

In this case two spots, corresponding to the potassium xanthogenates of methanol and ethanol respectively, are recognized clearly by ultra-violet light. Both spots appear at first yellowish in colour on spraying with Grote's reagent, but the spot of the latter alcohol turns brown in half an hour whereas that of the former still remains yellow. By using this method, 0·1 per cent of methanol contained in ethanol is easily detected. Limit of identification: methanol 18 γ, ethanol 25 γ.

The R_F values for alcohols, obtained by the potassium xanthogenate method, are as follows:

Methanol	0·23	*iso*Amyl alcohol	0·62
Ethanol	0·35	Benzyl alcohol	0 45
*iso*Propanol	0 44	Octyl alcohol	0 17
*iso*Butanol	0·54	*cyclo*Hexanol	0 64
n-Butanol	0·56	Ethylenechlorohydrin	0 91

Partition Paper Chromatography of Some Organic Acids

IN the course of studies on the metabolism of bacteria, our attention has been focused on the question of partition paper chromatography of organic acids, especially those occurring in living bacterial cells. The present communication describes an attempt to examine the possibility of detecting and resolving organic acids by use of paper chromatography.

The technique employed by us was essentially the same as that of R. Consden, A. H. Gordon and A. J. P. Martin[1]. As a developer, we used phenol saturated with water; as a stationary phase, we used water saturated with phenol. To prevent ionization of organic acids, the atmosphere of our chromatographic chamber was saturated with the vapour of formic acid (see J. W. H. Lugg and B. T. Overell[2]). The paper strips were placed after development in an oven at 110° C. for 15 min., or were dried at room temperature for 24 hr. Then the chromatograms were treated with a solution of a suitable indicator. It has been shown that 0·04 per cent (w/v) alcoholic solution of bromphenol blue gave the best results as regards the stability of revealed spots, although the bromthymol blue seemed to be more sensitive. The locations of some organic acids were also verified by their fluorescence in ultra-violet light.

Unfortunately, we have at our disposal only a limited number of organic acids known to be common metabolites of living cells. The experiments have been conducted both with aqueous solutions of single, chemically pure acids, and with their mixtures. The R_F values were determined as well as standard deviations and 95 per cent confidence intervals, which will be presented elsewhere.

We find that in concentrations ranging from 0·5 to 5·0 per cent (w/v or v/v) there was no apparent influence on R_F values of the acids examined. Although the size and intensity of the spots seem to be proportional to the concentration of acids present, we observed that some acids form more intense and larger spots than would be expected from their concentrations. No doubt this phenomenon is closely connected with the structure of the acid molecule in question.

We did not succeed in recovering uric acid, probably due to its insolubility in water. Among the organic acids under investigation the volatile ones (formic, acetic, propionic and camphoric acid) were not detectable on the chromatograms. In the case of halogenated derivatives of acetic acid, the R_F values were unstable and varied greatly from experiment to experiment.

The R_F values of the acids examined showed no differences greater than the experimental error when the experiments were carried out with one acid or with a mixture of acids. Some acids such as *p*-aminobenzoic, benzoic, salicylic, tannic, lactic and ascorbic gave a relatively high percentage of discrepant results, which were rejected in the calculation of mean R_F values. With an improved technique, better results would be expected (for example, that of F. A. Isherwood and C. S. Hanes[3]).

We have been interested to find a numerical relationship between the structure of a chemical group and its influence on R_F values of organic acids. From a comparison of R_F values of two acids the theoretical R_F value of a group constituting the difference between these acids may be calculated. In such a manner we have determined approximately so-called ΔR_F, that is, an increase or decrease of R_F value caused by incorporation of a given group, for the following chemical groups:

1. $\Delta R_F(C)^{I} = +1{\cdot}23$ (for the first C atom of aliphatic chain).
   $\Delta R_F(C)^{II} = +0{\cdot}20$ (for the second C atom of aliphatic chain).
   $\Delta R_F(C)^{III} = +0{\cdot}10$ (for the further C atoms of aliphatic chain).
2. $\Delta R_F(COOH)^{I} = +0{\cdot}55$ (for the first COOH-group).
   $\Delta R_F(COOH)^{II} = -0{\cdot}45$ (for the second COOH-group).
   $\Delta R_F(COOH)^{III} = -0{\cdot}25$ to $-0{\cdot}30$ (for the further COOH-groups).
3. $\Delta R_F(OH) = -0{\cdot}22$ (in the aliphatic acids).
4. $\Delta R_F(NH_2) = -0{\cdot}27$ (in the aliphatic acids).
5. ΔR_F(benzene ring) $= +1{\cdot}42$.
6. $\Delta R_F(COOH)$cycl. $= -0{\cdot}55$ (the same value in all positions).
7. $\Delta R_F(OH)$cycl. $= -0{\cdot}22$ (if attached to any atom of carbon of the benzene ring).
8. $\Delta R_F(OH)$cycl. $= \pm 0{\cdot}00$ (if present in a side-chain).
9. $\Delta R_F(NO_2)$cycl. $= -0{\cdot}15$ (in the case of picric acid).
10. $\Delta R_F(SO_3H)$cycl. $= -0{\cdot}48$ (if attached to benzene ring).
11. ΔR_F(N or NH or NH_2)cycl. $= \pm 0{\cdot}00$ (irrespectively whether present in the ring or in the side-chain).

It appears advantageous to control experimentally obtained results by comparison with the theoretical R_F values.

The mean R_F values for a number of acids were as follows: *p*-aminobenzoic, 0·87; ascorbic, 0·46; aspartic, 0·36; benzoic, 0·86; citric, 0·26; fumaric, 0·64; glucuronic, 0·22; lactic, 0·79; malic, 0·43; malonic, 0·54; mandelic, 0·86; nicotinic, 0·89; oxalic, 0·33; picric, 0·75; sulphosalicylic, 0·26; tannic, 0·19; tartaric, 0·21; pyruvic, 0·35.

Identification of Sulphonamides by Paper Partition Chromatography

The identification of sulphonamides in biological fluids is usually attempted by microscopical examination of crystals and by the use of various, rather non-specific, colour reactions[1]. Since it is common for only small quantities of fluid to be available, it was decided to investigate the possibilities of paper partition chromatography.

The method of ascending chromatography described by Williams and Kirby[2] was used in preference to the usual procedure, this method being more convenient when dealing with six or seven 'spots'. Unfortunately, no single solvent could be found which would separate all the sulphonamides to an extent permitting identification. It was found, however, that the sulphonamides tend to fall into two classes, namely, those separable with a basic solvent and those separable with an acidic solvent. By using either of or both these solvents, the sulphonamides can be separated and identified. The R_F values of some of the sulphonamides in common chemotherapeutic use are given in the accompanying table.

R_F Values

Sulphonamide	*n*-Butanol/ammonia	*n*-Butanol/acetic acid
Sulphaguanidine	0·43	0·36
Sulphathiazole	0·48	0·46
Sulphanilamide	0·56	0·42
Sulphadiazine	0·24	0·50
Sulphamezathine	0·48	0·48
Sulphamerazine	0·34	0·50
Sulphacetamide	0·71	0·44
Sulphapyridine	0·70	0·51

The solvents are prepared as follows:

(*a*) *Acid solvent.* 50 ml. of *n*-butanol is mixed with 15 ml. of glacial acetic acid and 60 ml. of distilled water. The mixture is well shaken in a separating funnel and allowed to separate. The lower aqueous layer is discarded and sufficient *p*-dimethylamino benzaldehyde added to the remaining solvent to give a concentration of approximately 0·5 per cent.

(*b*) *Basic solvent.* 40 ml. *n*-butanol is mixed with 10 ml. of ammonium hydroxide and 30 ml. water. The mixture is shaken up as with the acid solvent, separated and *p*-dimethylamino benzaldehyde added to the organic layer to give a concentration of approximately 0·5 per cent.

The paper used was a sheet of Whatman No. 1 filter paper measuring approximately 20 cm. × 25 cm. A base-line was drawn about 3 cm. from one end and approximately 0·01 ml. quantities (containing 5–15 gamma) of solutions of each of the sulphonamides in *N* hydrochloric acid spotted on the base line at intervals of 2–3 cm. At the same time an unknown sulphonamide solution was 'spotted' on the base line. The spots were then sprayed with Ehrlich's reagent (2 per cent *p*-diamethylamino benzaldehyde in hydrochloric acid) and the filter paper rolled into a cylinder and clipped at the top end with a paper clip.

Two such chromatograms were then placed in Petri dishes containing the solvents, each covered with a bell jar, and irrigation was by capillary attraction for 6–12 hr. Then the papers were removed and, if necessary, sprayed with Ehrlich's reagent. This has never been found necessary after the acid solvent has been used; but the spots usually become faint after irrigation with the basic solvent. From the position of the unknown spot on both chromatograms, the nature of the unknown can be determined.

Elastin from Human Tissue and from Ox Ligament

THE starting material for the majority of the reported analyses of elastin has been ox ligamentum nuchæ subjected to long periods of boiling in water, the simplest of the methods described by Stein and Miller[1].

Human aorta has been treated in this fashion, and also boiled in frequent changes of 1 per cent acetic acid, a treatment which has been proved by Gross[2] to remove all structurally intact collagen, as demonstrated by the electron microscope. A hydrolysate of material subjected to prolonged treatment by either of these methods shows on chromatography a far greater concentration of basic amino-acids and hydroxyproline than would be expected from "pure elastin" (cf. Bowes and Kenten[3], and Neuman[4]).

Similar chromatograms to those reported by Bowes and Kenten can, however, be obtained from hydrolysates of aorta tissue which has been boiled for five days with frequent changes of between 50 and 100 volumes of 40 per cent urea solution. It might therefore be concluded that certain collagenous substances are more difficult to remove from human tissue than from ox ligament; but that after the complete removal of such proteins the insoluble residue is very similar if not identical in both species, and to this the name 'elastin' could appropriately be given.

Doubt, however, is cast on the validity of this definition of elastin, since it has been shown that the resistance to solution in 40 per cent urea solution of elastin preparations from both ox and human tissues is not absolute, as reported by Stein and Miller, but is a function of the liquor ratio. The whole of an elastin preparation will pass into solution if the volume of the urea solution is raised to between 100 and 200 times that of the solid.

Similarly there are indications of heterogeneity in the residues after treatment with 50 volumes of urea solution. Differences in composition, notably with respect to proline, are observed between the material dissolved from these residues and that remaining after attack by pancreatic elastase[5].

The definition for elastin, therefore, now becomes rather vague. Under the electron microscope, certain branched and rather ill-defined structures are identified as collagen-free elastin. Chemical analysis shows that these preparations are still contaminated with material having some of the significant amino-acids of collagen. A chemical definition of purity based on insolubility in urea is also suspect, since the amount of urea available alone determines the extent of solution.

A fuller examination of the chemical analysis of various preparations obtained by the action of urea and of elastase on both human and ox tissues is in progress. These results, together with corresponding electron microscope studies undertaken in co-operation with the Department of Biomolecular Structure of this University, will be published elsewhere.

X-Ray Micro-radiography of Biological Specimens

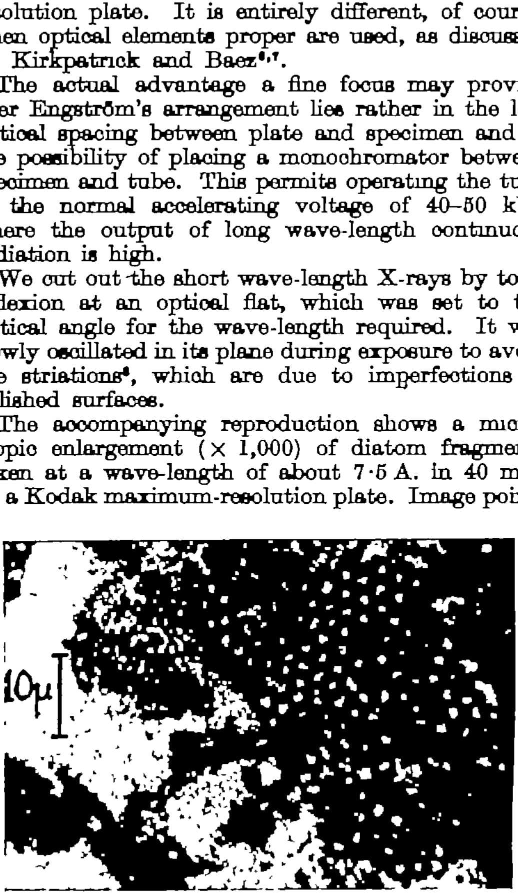
A HIGHLY loaded micro-focus X-ray tube[1,2] was used for taking X-ray photographs of microscopic specimens. Engström and others[3-5] have established a strong case for this kind of micro-radiography and have obtained remarkable photographs of microscopic sections in a wave-length range of 5–10 A. using a special tube with a focus of moderate size.

It can easily be shown that even with the fine focus now available ($4\,\mu \times 40\,\mu$) it is advisable, in this wave-length range, to rely entirely on optical magnification of shadow-graphs and to place the specimen close to a photographic plate of high resolution. For, in the case of direct shadow enlargements, the definition can never be better than the dimension of the focus, and even for a point focus at a reasonable distance from the specimen, it is limited by diffraction to less than the resolving power of a maximum resolution plate. It is entirely different, of course, when optical elements proper are used, as discussed by Kirkpatrick and Baez[6,7].

The actual advantage a fine focus may provide over Engström's arrangement lies rather in the less critical spacing between plate and specimen and in the possibility of placing a monochromator between specimen and tube. This permits operating the tube at the normal accelerating voltage of 40–50 kV., where the output of long wave-length continuous radiation is high.

We cut out the short wave-length X-rays by total reflexion at an optical flat, which was set to the critical angle for the wave-length required. It was slowly oscillated in its plane during exposure to avoid the striations[8], which are due to imperfections of polished surfaces.

The accompanying reproduction shows a microscopic enlargement (× 1,000) of diatom fragments taken at a wave-length of about 7·5 A. in 40 min. on a Kodak maximum-resolution plate. Image points



0·5 micron apart are clearly resolved. The specimen was deposited on a collodion film placed 0·2 mm. in front of the plate. The X-ray tube had a 10-micron aluminium window, and the space between this window and the plate was evacuated. The reflector was 4 cm. long and the specimen placed 16 cm. from the focus. These dimensions were chosen to make use of existing gear. The focus-specimen distance can be reduced to at least half without affecting the resolution. This would reduce the exposure time to about 10 min. Another factor of 2 could be gained by using a tungsten anti-cathode instead of the copper target of our tube. The glancing angle by which the X-rays are reflected, and hence λ(min.), changes slightly across the object plane. The effect is easily calculated and amounts to about 2 A./mm. across the specimen for a focus to specimen distance of 16 cm.

Phosphorus Trifluoride–Hæmoglobin

There are numerous examples of complex compounds formed by trivalent phosphorus compounds which have an electron pair available for the formation of dative bonds[1], and recently this knowledge has been extended by the preparation of phosphorus trifluoride complexes of divalent platinum[2]. There is a close analogy between the lower halides of phosphorus and carbon monoxide in such compounds, and this analogy has been strengthened by the recent preparation of the tetrakistrihalogenophosphine nickels, $Ni(PCl_3)_4$ [3], $Ni(PBr_3)_4$ [4], and $Ni(PF_3)_4$ [4]; the latter is a volatile liquid similar to nickel carbonyl, $Ni(CO)_4$. It was therefore thought that phosphorus trifluoride might form a complex with ferrohæmoglobin similar to the well-known covalent complexes with carbon monoxide, nitric oxide, *iso*cyanides, etc.[5]. The existence of such a phosphorus trifluoride–hæmoglobin compound has been established, providing further evidence for the covalent bonding ability of phosphorus trifluoride.

A solution of partially oxygenated human hæmoglobin was prepared (cf. ref. 5, p. 211) and portions of this solution were diluted with disodium hydrogen phosphate citric acid buffer solutions to give a hæmoglobin concentration about 1/200 that in whole blood. Hæmoglobin was then formed by reduction with sodium dithionate ($Na_2S_2O_4$), and portions of the solution were agitated with phosphorus trifluoride at various partial pressures in pure nitrogen. A pink colour, visually different from the colour of either oxyhæmoglobin or carbonmonoxyhæmoglobin, rapidly developed and the broad band of the hæmoglobin absorption spectrum centred around 560 mμ changed to give two sharp bands centred about 540 and 575 mμ; a hand spectroscope with a scale was used for detection. No change in colour or absorption bands was evident on addition of excess dithionate.

The formation of the phosphorus trifluoride–hæmoglobin complex is not critically dependent on the *p*H of the solution in the range 5·0–8·1. The complex is unstable, persisting for only a few minutes. In alkaline solutions, the rate of formation is slower and the rate of decomposition faster than in acid solutions, presumably due to the increase in the rate of hydrolysis of phosphorus trifluoride with increasing *p*H.

It has proved impossible to measure the absorption spectrum of the compound with any accuracy due to the rapid hydrolysis; but a rapid survey of the spectrum in the region from 520 to 590 mμ was made on a Beckman spectrophotometer. Comparison with the spectra of oxyhæmoglobin (peak maxima at 576–578 mμ and 540–542 mμ) and carbonmonoxyhæmoglobin (peak maxima at 568–572 mμ and 538–540 mμ) measured in the same conditions shows the close similarity of the phosphorus trifluoride hæmoglobin (peak maxima 574–577 mμ and 540–543 mμ) with the former. The intensity of the peaks appears to be similar and the α-peak is the sharper.

Again due to hydrolysis, estimation of the half-saturation pressure is impossible; however, the compound is readily formed with phosphorus trifluoride partial pressures of the order of 1 cm. mercury.

No evidence has been obtained for the formation of a hæmoglobin complex of nitrogen trifluoride, and the reported[6] cyanosis due to nitrogen trifluoride was probably due to impurities. The inability of nitrogen trifluoride to form a compound with hæmoglobin is probably due to the absence of vacant 2*d* orbitals in the nitrogen atom, so that there is no possibility of the π-bonding which occurs in the phosphorus trifluoride complexes, where there is a vacant 3*d* orbital in the phosphorus atom. The nitrogen trifluoride used in this work was kindly given by Prof. E. G. Rochow of Harvard University.

I am greatly indebted to Prof. Charles D. Coryell for his stimulating advice and for his contribution of samples of blood.

Free Amino Groups of Collagen

Using the technique originated by Sanger[1] for the determination of end-groups in proteins by reaction with dinitrofluorbenzene, no free α-amino- or imino-groups have been detected in ox hide collagen[2], even when the equivalent of 2–3 gm. dinitrophenyl-collagen was placed on the silica gel columns.

After heating in water at 70° C., and treating with alkali, or urea, a small number of α-amino groups were found.

Since collagen contains a considerable amount of proline, the dinitrophenyl derivative of which is unstable to acid hydrolysis, special efforts were made to detect this derivative. Recovery of dinitrophenyl-proline added to collagen, and from salmine treated with dinitrofluorbenzene, indicates that proline would have detected it if it had been present to the extent of one end-group per unit of 1,500,000.

Failure to detect an end-group in collagen suggests three possibilities: (1) that the molecular weight is very large—greater than 1,500,000 if proline is an end-group, and of the order of 2,000,000 or more if some other amino-acid forms the terminal group; (2) that the molecule has a cyclic structure; or (3) that the end-group is inaccessible to dinitrofluorbenzene, or is masked in some way by combination with some other group, or with carbohydrate. There is insufficient evidence available at present to indicate which, if any, of these hypotheses is correct; but the following observations may be made. Average molecular weights of up to 250,000 have been reported for gelatin[3]; it is known that a small number of peptide bonds are broken in the conversion of collagen to gelatin, hence the molecular weight of collagen might well be several times this figure. There is only a small amount of carbohydrate in collagen; but it is perhaps of interest to note that the amount of chondroitin sulphate estimated to be present in this collagen from its hexosamine content and the intensity of spots due to glucosamine and chondrosamine on paper chromatograms[4] corresponds approximately to one molecule of chondroitin sulphate per unit of 80,000, that is, in roughly twice the minimum molecular weight (39,000) calculated from the amino-acid composition[5].

Lysine content of collagen: 31 m.mol./100 gm.

In modified collagens, various end-groups were detected in small amounts (see table). With alkali-treated collagen, the small number of end-groups found does not represent the total number of peptide bonds broken, since about 5 per cent of the collagen was solubilized during the treatment, some as small peptides and some as comparatively large units[5]. These fractions are now being examined. Dispersion in formic acid has often been used as a method of obtaining 'soluble collagen'. The dinitrophenyl derivative of collagen treated with formic acid was soluble and resembled dinitrophenyl-gelatin rather than the other modified collagens.

Aspartic and glutamic acids were frequently found as end-groups of modified collagen, and it would appear that the peptide bonds involving the amino groups of these acids are particularly labile. Partridge[6,7] has also found that these acids are preferentially liberated in the partial hydrolysis of a number of proteins with weak acids.

The amounts of ϵ-dinitrophenyl-lysine isolated from all the collagens were appreciably less than the amounts corresponding to their lysine contents (see table). Even in gelatin, only about half the ϵ-amino groups of lysine reacted with dinitrofluorbenzene. Dinitrophenyl-hydroxylysine was also detected; evidence suggests that some of the side-chain amino groups of this amino-acid were also unreactive to dinitrofluorbenzene. Porter[8] also found that the ϵ-amino groups of a number of soluble proteins did not react with dinitrofluorbenzene, but that after denaturation all became available. This is not so with collagen, and there is some evidence that heat denaturation actually causes a slight decrease in the number of ϵ-amino groups reacting. With soluble proteins, denaturation is generally considered to cause unfolding of the polypeptide chains. Collagen is already in the extended form, and heat denaturation, which causes considerable shrinkage, probably involves folding of the chains, which may decrease the availability of amino groups.

Direct Oxidation of Glucose by *Aerobacter* sp.

A PRECISE picture of a pathway of glucose metabolism existing in addition to the classical scheme proposed by Embden, Meyerhof, Parnas, Cori and many others is slowly emerging from experiments on carbohydrate metabolism[1–7]. This route, proceeding by way of 6-phosphogluconate and its derivatives, is called 'direct'. Some years ago, a study of aerobic and anaerobic acid formation with nitrogen-poor bacteria led one of us (J. D. L.) to suppose that, beside the classical respiration by triose phosphate dehydrogenase, our strain could equally well oxidize glucose by way of phosphogluconate, gluconate or a non-phosphorylative process[8].

We now report experiments demonstrating that in *Aerobacter* sp. a pathway of glucose metabolism exists in which gluconate (most probably as 6-phosphogluconate) and its derivatives are involved. (We wish here to direct attention to the the fact that the strain, obtained from the Biochemical Laboratory, Helsinki, used by one of us (J. D. L.) in the earlier experiments in the latter and later in this Laboratory, was formerly erroneously called *E. coli*. It exhibits the properties of an *Aerobacter*.)

The bacteria were cultured in a synthetic medium containing dipotassium hydrogen phosphate, sodium chloride, magnesium and ammonium sulphate and carbohydrates or their derivatives (D-glucose, sodium D-gluconate, sodium 2-keto-D-gluconate, D-ribose). Various substances believed to partake in the direct metabolism of glucose were added to the centrifuged and washed bacteria, suspended in phosphate buffer, and the oxygen consumption was measured by means of the Warburg respirometer. No oxidation could be observed with the following substrates: sodium 5-keto-gluconate, D-arabinose, sodium D-arabonate, sodium D-ribonate. The fact that D-arabinose and D-ribonate are not oxidized is not in agreement with the original hypothesis by Dickens[3], although it might be asserted that the corresponding D-arabokinase and D-ribonokinase are absent from the cellular enzymic equipment.

The following substances were always fairly rapidly oxidized with or without an initial induction phase: D-glucose, sodium D-gluconate, sodium 2-keto-D-gluconate, D-ribose, L-arabinose, sodium D-glucuronate, D-xylose. The routes of breakdown of L-arabinose and D-xylose are obscure, suggesting the need for a study of the interconversion of pentoses by means of their phosphorylated derivatives, as in the well-known fructose-glucose-galactose transformations.

Since oxidative decomposition plays an important part in 'direct' glucose metabolism, we also investigated the influence of aerobic and anaerobic cultural conditions on the behaviour of the enzymic systems involved. Our experiments demonstrate that the enzyme systems which metabolize glucose by way of gluconate are not formed preferentially in aerobic culture conditions, but are also very actively present in anaerobically cultured bacteria. The cells grown aerobically oxidize their substrates faster, however, probably because of adaptive formation of cytochromes in presence of oxygen[8]. The oxidation of glucose never showed an initial lag phase and was independent of the substrate in the previous culture. Sodium D-glucuronate, D-xylose and L-arabinose were only oxidized after a considerable induction phase, indicating the formation of adaptive enzymes. The accompanying table shows the presence or absence of the initial lag phase in the oxidation of a substrate, according to the previous cultural conditions.

Substrate for respiration	Bacteria cultured on			
	D-Glucose	D-gluconate	2-Keto-D-gluconate	D-Ribose
D-Glucose	–	–	–	–
D-gluconate	+	–	+	+
2-Keto-D-gluconate	+	+	–	+
D-Ribose	+	+	+	–

+, Induction phase; –, no induction phase.

These results may be explained by the adaptive nature of the kinases for gluconate[7], 2-ketogluconate and ribose, while the enzymes catalysing the reactions glucose → glucose-6 phosphate → 6-phosphogluconate → 6-phospho-2-ketogluconate should be constitutive, since the latter substrates are oxidized at the same rate, once the adaptive kinase has been formed. The further breakdown of 6-phospho-2-ketogluconate and the reactions leading to 5-phosphoribose are by no means clear[3,10,11].

We hope to present in the near future a closer investigation of this and related problems. A full account of this work is to be published elsewhere.

In vitro Fungistatic Action of Phenanthrolines against Pathogenic Fungi

Working with a diffusion technique described elsewhere[1], I found in August 1948 that a number of phenanthrolines had fungistatic properties, until then unknown. *o*-Phenanthroline, highly bacteriostatic for Gram-positive and Gram-negative bacteria, has a stronger growth-inhibiting effect against *Ctenomyces interdigitalis* (= *Trichophyton interdigitale*) than *p*- or *m*-phenanthroline. Alkylation of *o*-phenanthroline increased its fungistatic action. 2,9-Dimethyl-*o*-phenanthroline proved to be the most potent fungistatic agent of all phenanthrolines tested. Further alkylation or chlorination of the latter substance resulted in a reduction of its fungistatic action. 2,9-Dimethyl-*o*-phenanthroline was still effective in the test mentioned above when used in $M/1600$ solution. The fungistatic properties of this compound were not affected by adding serum to the medium, as happens with a number of fatty acids and their sodium salts. This substance also showed marked bacteriostatic properties against Gram-positive bacteria.

The spectrum of effectiveness of 2,9-dimethyl-*o*-phenanthroline includes numerous genera and species of fungi pathogenic for man and animals, such as *Ctenomyces interdigitalis*, *Trichophyton rubrum*, *T. tonsurans*, *T. schönleini*, *Sabouraudites audouini* (= *Microsporum audouini*), *S. canis*, *Epidermophyton floccosum*, *Candida* species, *Nocardia* species, *Hormodendrum pedrosoi*, *H. compactum*, *Sporotrichum schenckii*, *Piedraia sarmentoi*, *Phialophora verrucosa*, etc.

Recently, *Aleurisma tulanense* (= *Blastomyces dermatitidis*), freshly isolated from a case of cutaneous North American blastomycosis, was tested against 2,9-dimethyl-*o*-phenanthroline. A dilution method described by Kolmer and Boerner[2] was used for this purpose. This fungus did not grow on a medium containing Sabouraud glucose agar, 'Difco' and 10 per cent serum with 0·002 per cent 2,9-dimethyl-*o*-phenanthroline. Growth was strongly inhibited by this substance in concentrations ranging from 0·001 to 0·0005 per cent. Normal growth occurred if the medium contained less than 0·0005 per cent of the substance.

Effect of Oxidized *d*-Limonene on Micro-organisms

During our studies on microbiological problems in the citrus industry, we found it necessary to study the effect of essential oils on micro-organisms. As a first step in this study, we investigated in a synthetic medium the influence of *d*-limonene, which constitutes more than 90 per cent of the orange essential oil, on micro-organisms normally present on the surface of oranges.

It was shown in this way that *d*-limonene, freshly distilled over sodium, has no inhibitive action on the micro-organisms tested (a strain of *Sacar. elipsoideus, Wilia hansenula, Oidium lactis*) when added to the synthetic medium. However, the vapours of this limonene exhibit a bacteriostatic effect.

When exposed to air, *d*-limonene reveals inhibitive properties, which increase with the duration of exposure. Also, when samples of the oxidized limonene are tested for the presence of peroxides by the potassium iodide method, iodine is liberated and by titration an increase of peroxide formation may be shown.

Quantitative estimation of the inhibition by Hinshelwood's method[1] has revealed that this action is marked only by shifting the time of the lag phase, without any influence on the logarithmic growth phase and the number of the total population. When plotting the lag time against the increased doses of an oxidized *d*-limonene, an adsorption isotherm curve is obtained, similar to those obtained by Hinshelwood. Samples of *d*-limonene, taken at different times of exposure to air, give a set of such curves with the point of lethal dose decreasing with increasing time of oxidation.

The oxidized *d*-limonene, in the aqueous nutrient medium, however, loses its inhibitive properties on keeping. This decrease of inhibition is enhanced by the presence of *l*-ascorbic acid in the medium.

Steam distillation of oxidized *d*-limonene in presence of sodium hydroxide also destroys its inhibitive properties. Neither the distillate nor the resinous viscous residue added in adequate doses to the synthetic medium shows any inhibition of the micro-organisms tested.

Recent advances in organic chemistry[2] show that the fixation of an oxygen molecule from air in *d*-limonene will take place by forming a peroxide bond. This oxidation can be considered as an 'initiation reaction', which will catalyse a second reaction, namely, a polymerization of the activated terpen radicals. Hence, we may assume that the first reaction is responsible for the appearance of the inhibitive properties of limonene exposed to air. This accords with the generally known toxic properties of peroxides or epoxides. (However, the possibility that the second reaction may influence the specific toxicity of any peroxide formed cannot be excluded.)

There is a lack of precise chemical–physical data as to the mechanisms of the two reactions. When in our experiments the oxidation of *d*-limonene was carried out in different physical conditions, quantitative estimation of the reaction showed a change in the value of the parameters of the adsorption isotherms. A more detailed account of this work will be published elsewhere.

The fact that the oxidation is catalysed by light and chlorophyll[3] suggests that the reaction is possibly of biological importance, and experiments in this direction are under way.

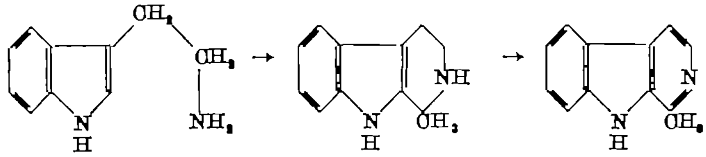
Isolation of Tetrahydroharman from *Petalostyles labicheoides*

In the course of a comprehensive study of the alkaloids in Australian Leguminosae, the examination of *Petalostyles labicheoides* was undertaken. This erect and bushy shrub grows to a height of several feet, and is found mainly in northern New South Wales and in Queensland. Alkaloids were detected in this plant in the course of the extensive field tests carried out by Mr. L. J. Webb[1], who kindly arranged for a quantity of the plant to be supplied for more intensive investigation.

The finely ground and dried plant was first intracted with chloroform to remove various colouring matters, after which the alkaloid was extracted with methanol. Concentration of the extract gave a thick syrup which was taken up in 1 per cent hydrochloric acid. The acid solution was basified, and the precipitated alkaloid extracted with ether. (The ether-insoluble material probably contained another (unstable) alkaloid, which, however, has so far resisted all attempts at purification.) The crude crystalline material obtained on evaporation was dissolved in anhydrous ether and purified by chromatography on alumina. The pure alkaloid formed very pale yellow prisms or needles, of melting point 178–180° (found: C, 77·5; H, 7·7; calc. for $C_{12}H_{14}N_2$; C, 77·4; H, 7·6 per cent). The melting point, analysis and ultra-violet absorption spectrum, the last kindly determined by Mr. R. S. Pearce (maxima at 2255 A., log ϵ, 4·57; 2830 A., log ϵ, 3·90; and 2910 A., log ϵ, 3·82), indicated that the alkaloid was tetrahydroharman (II, melting point in the literature, 179–180° [2]). The benzoyl derivative first separated from ether as colourless crystals, melting point 165–167° (in the literature, 168–169°), but on recrystallization from 50 per cent alcohol it formed long needles of melting point 194–195° (found: C, 78·55; H, 6·0; calc. for $C_{19}H_{18}N_2O$; C, 78·25; H, 5·8 per cent). This was evidently a dimorphic form. The identity of the alkaloid was confirmed by the preparation of the hydrochloride, melting point (decomp.) 265° (in the literature, 267° (decomp.)), and by a mixed melting point comparison with an authentic synthetic specimen kindly presented by Dr. R. H. F. Manske. Finally, the ultra-violet absorption spectrum of the natural product coincided exactly with that of the synthetic material.



(I) (II) (III)

Tetrahydroharman (II) does not seem to have been obtained previously from natural sources, and this proof of its occurrence in Nature is of interest in connexion with studies of the biogenesis of alkaloids. It has often been suggested[3], for example, that harman (III) and related β-carboline alkaloids, are synthesized in the plant from tryptamine (I), or tryptophan, by condensation with acetaldehyde to give (II), and subsequent dehydrogenation to (III). Tryptamine (I) has already been shown[4] to occur in several species of the genus *Acacia* (Leguminosae), and G. Hahn and H. Ludewig[5] have demonstrated that tryptamine readily condenses with acetaldehyde *in vitro* and under 'physiological' conditions of temperature and *p*H. Harman (III) has, of course, been isolated from several plants[6], and the present isolation of tetrahydroharman (II) from a natural source completes the series and supports the speculations of Robinson and others[3] in a very satisfactory way.

Note added on July 19. It has recently been announced[7] that racemic tetrahydroharman has also been isolated from *Elaeagnus augustifolia*.

Alkaline Decomposition of Amino-acids

In the course of an examination of the amino-acid composition of soil hydrolysates by the paper chromatography technique, it was noticed that alkaline hydrolysates of soil contained greater amounts of α-amino-*n*-butyric acid than did acid hydrolysates[1]. Further work indicated that alkaline hydrolysates also contained greater amounts of glycine. These results suggested that, under the conditions commonly employed for the hydrolysis of proteins with alkali, glycine and α-amino-*n*-butyric acid are formed by decomposition of other amino-acids. Paper chromatographic examination of acid (6 *N* hydrochloric acid) and alkaline (5 *N* sodium hydroxide) hydrolysates of casein supported this, since α-amino-*n*-butyric acid was found in the alkaline, but not in the acid, hydrolysate, and the glycine spot on chromatograms of the alkaline hydrolysate was distinctly stronger than the corresponding spot on comparable chromatograms of the acid hydrolysate.

These findings led to a study of the effect of hot sodium and barium hydroxides on various amino-acids. Results so far obtained have shown that, under the conditions generally used for hydrolysis of proteins with alkali, threonine yields glycine and α-amino-*n*-butyric acid, serine yields glycine and alanine, and cysteine and cystine yield alanine. An attempt is now being made to follow these decompositions quantitatively. Preliminary results indicate that, after treatment of threonine with 5 *N* sodium hydroxide in a sealed tube at 105° C. for 24 hr., about 1–3 per cent of the original threonine nitrogen is present as α-amino-*n*-butyric acid and 60–70 per cent as glycine.

Full details of this work will be published later.

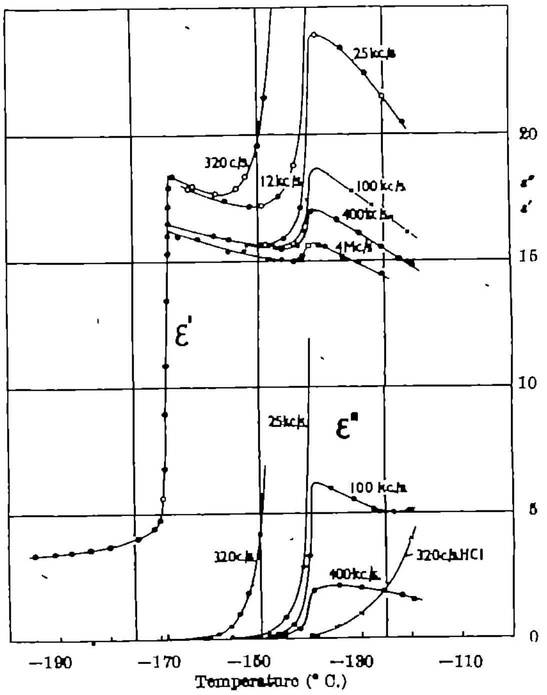
Dielectric Properties of a Sample of Deuterium Chloride containing an Impurity

Following a fairly extensive study of the dielectric properties of solid hydrogen chloride in this Laboratory[1], it was proposed to investigate the deuterated form. While hydrogen chloride was prepared by action of strong sulphuric acid on sodium chloride, deuterium chloride was obtained by dropping heavy water on thionyl chloride, the other product of the reaction being sulphur dioxide.



The first sample of deuterium chloride studied showed anomalous properties when compared with hydrogen chloride, due evidently to the presence of an impurity. The variation of ε' and ε'' with temperature for this sample are shown in the accompanying graph. As can be seen, the impurity causes a further transition point of first order to appear at − 140·5° C., that is, some 28° higher than the transition point corresponding to pure deuterium chloride, which, judging by the steepness of the rise in ε' and the value of the transition temperature itself (− 168·5° C.) does not appear to be affected by the presence of the impurity. Repeated distillation progressively reduced the magnitude of the effect, without noticeably changing the temperature of either transition. The effect decreases with increasing frequency, so that it is scarcely observable at 4 Mc./s. A twenty- to thirty-fold increase in the D.C. conductivity was also observed at the higher transition.

The properties of solid sulphur dioxide have not been previously investigated. As it was suspected that this substance was in fact the impurity, ε' and ε'' were measured at various frequencies between 80 c./s. and 6 Mc./s. over a temperature range from − 195° C. to its melting-point (− 10·0° C.). However, sulphur dioxide does not show any dispersion or transition effect in this frequency- and temperature-range.

Nature of the Transition in Carbon Tetrabromide

MANY transitions in solids have in the past been regarded as being due to, or accompanied by, the onset of ionic or molecular rotation. There is, however, little convincing evidence that ions or molecules can rotate *freely* in crystal lattices. The balance of available data is against this interpretation of transitions, though it is clear from studies of the dielectric constant that, at many transitions in molecular solids with polar molecules, the molecules acquire much greater orientational freedom on passing into the high-temperature form.

In principle, information about the molecular or ionic motion can be obtained from the values of c_v, which can be derived from experimental measurements of c_p, the coefficient of expansion (α), and the isothermal compressibility (β), using the well-known formula $c_p - c_v = T\alpha^2 V/\beta$. This method has been applied to the transition (λ-point) in ammonium chloride by Lawson[1]. By combining his measurements of β with existing values of c_p and α, he showed that, above the transition, c_v is sufficiently near $9R$ cal./mole to enable one to say with certainty that the ammonium ions do not, in fact, rotate above the λ-point, but rather continue to undergo torsional oscillations in three degrees of freedom which are approximately simple harmonic. This conclusion has since been confirmed in other ways[2,3].

We have applied this method to the first-order transition in carbon tetrabromide at 46·9° C. This transition gives rise to a much more symmetrical high-temperature form and is accompanied by a considerable increase of entropy. A number of transitions in solids composed of molecules of high symmetry are probably similar in these respects. It is therefore of interest that our results definitely show that the carbon tetrabromide molecules do not rotate freely in the high-temperature form.

The isothermal compressibility β was measured directly at three temperatures by applying pressures between 15 and 50 atmospheres, which are sufficiently low for the figures so obtained to be regarded as the limiting values at one atmosphere. We have also determined c_p above and below the transition and the heat of transition (using an adiabatic calorimeter), and α. From the values of c_v calculated from these results, we have deducted $c_{v(\text{int})}$, the contribution from the intramolecular vibrations, to give $c_{v(\text{res})}$, the contribution from the lattice vibrations and the torsional oscillations or rotation of the molecules. The results are summarized in Table 1, v is the specific volume.

Table 1

t (° C.)	v	$\alpha\times10^5$	$\beta\times10^6$ atm.$^{-1}$	c_p	c_v	$c_{v(\text{int})}$	$c_{v(\text{res})}$
0	0·2836	3·61	24·5	28·25	24·95	13 23	11 7
37·7	0·2882	5·05	29·9	31·70	25·55	14·05	11·5
55·8	0 3119	5·82	38·7	33 0	25·8	14·33	11·5

It is difficult to assess the uncertainty in the values of $c_{v(\text{res})}$ arising from the accumulation of experimental errors in the quantities used in calculating them, but it should not exceed ± 0·5 cal./mole. Since at the temperatures concerned the contribution to $c_{v(\text{res})}$ from the lattice vibrations must be very nearly $3R$ cal./mole, the figures definitely exclude free molecular rotation in the high-temperature form, which would require $c_{v(\text{res})}$ to be $9/2\ R$ cal./mole. On the other hand, the values of $c_{v(\text{res})}$ are so near $6R$ (= 11·9) cal./mole that it is probable that both above and below the transition the molecules undergo torsional oscillations in three degrees of freedom with approximately simple harmonic motion. From calculations of the thermodynamic properties of restricted rotators, our results could also mean that the rotation of the molecules is impeded by a barrier of such a height that in the temperature-range studied the contribution to $c_{v(\text{res})}$ from the torsional oscillations has roughly the maximum possible value. It would be interesting to know how $c_{v(\text{res})}$ changes as the temperature is further increased; but unfortunately the range between the transition point and the melting point is only about 40°. But in any event the conclusions that the molecules do not rotate *freely* in the high-temperature form, and that there is essentially no change at the transition point in the type of motion they undergo, seem inescapable.

The figure we have obtained for the heat of transition is rather different from that reported by Frederick and Hildebrand[4]; but it gives a value for the entropy of transition which is almost the same as that for the transition in carbon tetrachloride. In Table 2 are given values for the entropies of transition and fusion, and also the ratio T_{tr}/T_m (that is, of the transition temperature to the melting point) for carbon tetrafluoride, tetrachloride, and tetrabromide. The close similarity between the figures for the three substances strongly suggests that the nature of the transitions in them is the same, and that the conclusions we have reached about the tetrabromide are true also of the tetrafluoride and tetrachloride. A further similarity between the three transitions is that at none of them is there a significant change in the heat capacity at constant *pressure*.

Table 2

	CF_4	CCl_4	CBr_4
T_{tr}/T_m	0·852	0·901	0·881
ΔS_{trans}	4·64	4·86	4·98
ΔS_{fusion}	1·87	2·40	2·60

Finally, we may add that we have also measured the coefficient of expansion and compressibility of ammonium chloride above and below the λ-point (— 30·5°). Our results lead to values of c_v of 18·5 cal./mole at — 44·55°, and 18·7 cal./mole at — 19·31° and 0°. These figures fit in very well with those reported by Lawson[1], and confirm the conclusion he reached about the nature of the transition in this substance.

A full account of this work will be published elsewhere.

Solid Phase Determinations in the System Aluminium Sulphate/Sulphuric Acid/Water using Tracer Technique

In the system aluminium sulphate/sulphuric acid/water, the solid phase in the range 50–60 per cent sulphuric acid has been reported to be either $Al_2(SO_4)_3.9H_2O$ [1,2] or $Al_2(SO_4)_3.10H_2O$ [3] at temperatures between 20° and 60°, the composition of this solid being deduced by the Schreinemakers[4] method of tie-line convergence. However, in view of (a) the high molecular weight of aluminium sulphate compared with sulphuric acid and water, (b) the relative position in the equilateral triangle of the solubility curve, (c) inaccuracy in the position of the solution and moist solid points owing to the well-known difficulty of determining sulphuric acid in presence of aluminium sulphate, the published tie-lines show equally good convergence at points representing the 8, 9 or 10 hydrates or the 1 : 1 acid sulphate with eleven to thirteen molecules of water of crystallization.

This and similar cases[5] of ambiguity may be resolved by adding to the solubility mixture a suitable indicator substance which remains throughout in the liquid phase. Provided this indicator does not significantly alter the phase equilibrium and can be determined accurately in trace quantities, then the composition of the moist solid phase can be corrected for the contaminating liquid phase. Radioactive cæsium sulphate has been found to fulfil these severe conditions very well: only 0·05 c.c. of 0·045 per cent aqueous solution of approximately 15 μC. activity was required in a 50-gm. solubility mixture. This was not added until after the ternary mixture had been brought to equilibrium at 30° to avoid any co-precipitation of the tracer with the solid phase. The saturated solution and moist solid phase after convenient dilution were analysed for aluminium by precipitation with 8-hydroxyquinoline, for sulphuric acid by an accurate titration procedure, while counts were carried out in Type *M*6 Geiger–Muller liquid counters. Self-absorption errors were negligible because the counted solutions, after dilution with an equal volume of water, gave exactly half the original count. The solid phase was shown in this way to have the composition 51·4 per cent $Al_2(SO_4)_3$, 15·9 per cent H_2SO_4, 32·7 per cent H_2O, and must therefore be $Al_2(SO_4)_3.H_2SO_4.12H_2O$. This composition has been confirmed by using trace quantities of manganous sulphate as indicator, the manganese being determined colorimetrically as permanganate. The composition in this case was 51·5/15·1/33·4. It is surprising that this acid sulphate can be isolated in the pure state by simple filtration and thorough washing with 'Analar' acetone under anhydrous conditions, the composition of the dry 50° product being 51·4/15·1/33·5.

Other acid sulphates of composition 1/1/8 (two forms) and 1/1/2 have been encountered in this system, and full details will be published shortly elsewhere in collaboration with Prof. H. Bassett.

Electrical Conductivity and Magnetic Susceptibility of Ovalene

Ovalene ($C_{32}H_{14}$) has the most compact configuration of rings among the condensed aromatic compounds which have so far been obtained. From this point of view, it is of interest to know the electrical and magnetic properties to be attributed to the π-electrons of this molecule.

Ovalene was synthesized by the method of Clar[1] with modifications, and purified by repeated sublimation *in vacuo*. The measurement of the electrical conductivity as well as the magnetic susceptibility was carried out with a powder specimen. The electrical conductivity σ can be expressed as $\sigma = \sigma_0 \exp(-\Delta\epsilon/2kT)$, in the same manner as for the other condensed aromatic compounds[2]. The values of σ at 15° C. and Δε were found to be $4 \cdot 4 \times 10^{-16}$ ohm^{-1}.-cm.$^{-1}$ and 1·13 eV. respectively. The electrical conductivity of ovalene is less than that of violanthrone or *iso*violanthrone which were reported in the previous paper. In a series of measurements on a number of the condensed aromatic compounds, we have found that the electrical conductivity depends mainly on the number of π-electrons alone, and not on the configuration of the rings. On the other hand, the magnetic susceptibility is largely influenced by the shape of the molecule.

Molecular susceptibility was found to be $\chi_M = -(353 \cdot 8 \pm 2 \cdot 8) \times 10^{-6}$, by Gouy's method. $\chi_M = \frac{1}{3}(K_1 + K_2 + K_3)$ can be assumed, where K_1 and K_2 are the molecular susceptibilities along two directions in the plane of the rings and K_3 is that perpendicular to the plane. It can also be assumed that $K_1 = K_2 = \Sigma\chi(C=) + \Sigma\chi(H)$, and calculated from Pascal's constants on the basis of spherical symmetry. H. Shiba and G. Hazato[3] have shown that it is a good approximation to put $\chi(C=) = \chi(C) + \frac{1}{4}\lambda($diethylene linkage) = $-3{\cdot}36 \times 10^{-6}$, for this purpose. From these assumptions, the magnetic anistropy $\Delta K = K_3 - K_1$ was found to be $-615{\cdot}9 \times 10^{-6}$ for ovalene. This is a very high value. The contribution of each π-electron to the magnetic anisotropy can be expressed, conventionally, by the classical theory, $\Delta K = -(Ne^2/4mc^2)\sum_{\pi}\bar{r}^2$, where $\bar{r}$ is the mean radius of a circular orbit of a π-electron. For ovalene, $\bar{r}$ is calculated to be 2·12 A. This is also a high value, when it is remembered that $\bar{r}$ is 1·44 A. for benzene, 1·57 A. for naphthalene, 1·63 A. for anthracene and 1·86 A. for pyrene, where these values were calculated by the same method as for ovalene from specific susceptibility data in the literature, which do not differ seriously from the values obtained with single crystals[4].

Physical Basis of Internal Calorimetry

THE technique of 'internal calorimetry', a development of Gibbs's 'heated thermocouple' method[1], was devised for the measurement of blood flow in living tissues. The instrument consists of a small constantan filament connected to a source of electrical potential, variable at will. An attached thermocouple records the filament temperature. The energy required to maintain thermal equilibrium with the instrument embedded in the experimental material is recorded electrically. Its relation to blood flow has already been described[2]; our present concern, however, is with the non-circulatory heat losses from the filament.

With a recorder embedded in a gel—5 per cent gelatine in water—and heated 1° C. above ambient temperature, temperatures were measured thermoelectrically along a line perpendicular to the filament and also back along the leads. Temperatures were less than 0·01° C. in excess of the ambient temperature at a point in the gel 5 mm. from the filament and at a point on the wire distant 1 cm. from the filament.

It can be shown mathematically[3] that, with an electrically heated spherical source of heat in an infinite mass of material, a steady state is approached in which the relation between heat production and heat loss is represented by the equation:

$$I^2R = 4K.\pi.r\theta$$

(where K is thermal conductivity of the substance, r is radius of sphere, θ is temperature elevation of sphere, I is heating current and R is heating filament resistance). Where θ, r and R are fixed, I^2/K is thus constant.

That a similar relation may be applied to the present work was demonstrated using a standard instrument to record in air, chloroform, 'Vaseline', glycerine, water and mercury. Temperature was carefully controlled and convection errors eliminated by methods similar to those of Read and Lloyd[4]. In each case, the value of I^2 for $\theta = 1°$ C. was determined. Taking the values of K as given in the "International Critical Tables", the value of I^2/K was obtained for each substance and found to be virtually constant at $14{\cdot}0 \times 10^4$ (± 1 per cent). This ceased to be true if the depth of insertion or the bulk of fluid was not sufficient. The limits determined in 5 per cent gelatine, however, were 1 cm. depth of insertion and 5 mm. of substance surrounding the thermocouple.

It was thus shown, under these experimental conditions, that with θ constant, $I^2R \propto K$. In further experiments where K was constant, the relation between θ and I^2R was investigated and found to be linear except when θ was so large that the limiting conditions were exceeded.

These findings facilitate the standardization of blood-flow recorders in a manner to be described elsewhere. Moreover, they show that the method of 'internal calorimetry' may be used as a simple, quick means of measuring thermal conductivities, particularly in animal tissues.

Effect of Tension on Water Absorption by Hair

IT seems to be generally assumed that the application of tensile stress to a textile fibre should *reduce* the amount of absorbed water in equilibrium with water vapour in the atmosphere at a given value of the relative humidity[1]. This assumption would appear to be substantiated by the recent work of White and Stam[2] on human hair, in which a substantially reversible reduction of water content amounting to 50 per cent was found to occur on the application of a tensile stress of approximately 120 kgm./cm.[2].

On the other hand, for vulcanized rubber swollen in organic solvents, the equilibrium solvent concentration is *increased* by tensile stresses and reduced by compressive stresses[3]. This result is well established experimentally, and is in quantitative agreement with the statistical theory of the swollen molecular network[4,5].

In view of the opposite nature of these reported effects for fibres and for rubber, for which no immediate explanation is apparent, it seemed worth while to re-examine the question of the absorption of water by fibres under stress.

A general theory of the phenomenon may be derived by a simple extension of the usual thermodynamic treatment of swelling pressures. From such a theory Barkas[6] has obtained a relation which, in the case of a simple tensile stress, may be written:

$$s_X\,dX = -v\,dp, \qquad (1)$$

where s_X is the fractional increment of length in the direction of the stress X due to the absorption of 1 gm. of liquid, and v is the specific volume of the vapour at the pressure p. This equation relates the change dp in vapour pressure at equilibrium to the change dX in the stress; the corresponding change in water content, at constant vapour pressure, is then readily obtained from the vapour-pressure isotherm. It is seen from (1) that if s_X is positive, that is, if liquid absorption is accompanied by an increase of length in the direction of the stress, then dp is negative. This means that the vapour pressure (at constant liquid content) is lowered, so that at constant vapour pressure the liquid absorption is increased. This result should certainly apply in the case of hair, for which s_X is known to be positive.

In White and Stam's work the water content was determined indirectly from the measured dimensional changes of the fibre. I have repeated their experiments, using horsehair, which on account of its larger diameter permitted the water absorption to be determined more directly by weighing. Eight hairs, having a total length of 3·6 metres, were stretched by means of springs on a frame which was suspended from the arm of a balance in a temperature- and humidity-controlled vessel, the temperature being 24·0° C. and the relative humidity 75·5 per cent. The procedure was to weigh the assembly with the stress alternately applied and removed, time being allowed after each change for the attainment of equilibrium. The results are given below, each figure being the mean of four or five readings.

Tension per single hair (gm.)	Tension per single hair (kgm./cm.^{2})	Total wt. of hair (gm.)	Wt increase on stressing (% of dry weight)
149	460	0 1519$_0$	0 38
0	0	0 1514$_1$	
82	250	0·1515$_5$	0·17
0	0	0 1513$_0$	

The change in water content on applying the stress, though small, was consistent and reproducible. It was in the opposite direction to that found by White and Stam. To within the experimental error, the effect was proportional to the stress, the weight increments being in the ratio 2·2 to 1 for stresses in the ratio 1·8 to 1.

An estimate of the theoretical increment of water absorption may be made by using White and Stam's data for the longitudinal swelling. For 75 per cent relative humidity, the value obtained for s_X is 0·028 cm./gm. For a stress increase of 460 kgm./cm.^{2}, equation (1) then gives a change in relative vapour pressure (dp/p_0) of 0·0069. From Chamberlain and Speakman's vapour pressure curve[7], the corresponding change in water content (referred to the dry weight) is 0·23 per cent, compared with the experimental figure of 0·38 per cent. While the quantitative significance of this comparison is questionable, in view of the experimental uncertainty, there seems no doubt that the theory gives a satisfactory interpretation of the phenomenon, at least in order of magnitude.

Ultrasonic Velocity in Potassium Chloride Solutions in the Region of their Negative Viscosities

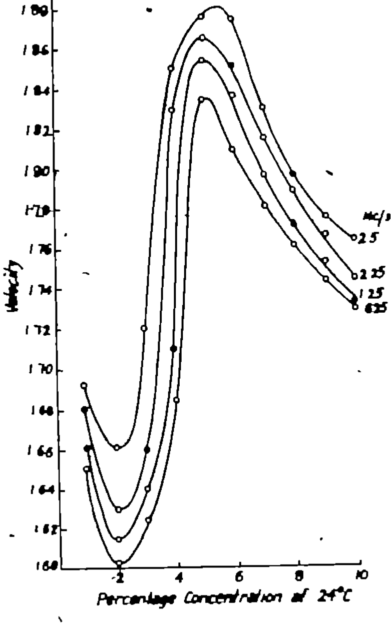
IT was observed by Poiseuille[1], Hubener[2], Sprung[3], Slotte[4] and others, that when substances like ammonium iodide, potassium chloride, etc., are dissolved in water, the viscosity of water is lowered. This phenomenon has since been known as 'negative viscosity'. The compressibility of aqueous solutions of electrolytes has been studied by Gibson[5], Falkenhagen and Bachem[6], Szalay[7] and others, and they have derived expressions for the relationship between the concentration of electrolyte solutions and their compressibilities. The existing data show that the compressibility continuously decreases as the concentration of electrolytes is increased. But these observations are confined to the positive region of viscosity. In the present communication we record our observations on the ultrasonic velocity in potassium chloride at low concentrations at 24°. The ultrasonic energy was obtained from a quartz disk and was converted into electrical energy by a similar quartz crystal for detection. The apparatus has been described elsewhere[8]. The slab can be rotated, resulting in a variation in the amplitude of the transmitted energy as recorded on the oscillograph screen. The minimum in the energy is due to the total reflexion of the transmitted energy, as the angle of refraction in the solid is greater than that of incidence. The refractive index at the discontinuity is:

$$n = \sin \theta_l / \sin \theta_s = V_l / V_s,$$

where θ_l and θ_s are the angles that the wave-train makes with the normal in the solid and the liquid respectively. V_s is the velocity in the solid, which can be determined in advance by using a liquid with known velocity. At total reflexion of the waves, due to the rotation of the slab,

$$V_\theta = V_s \sin \theta_l, \quad \text{since } \theta_s = 90°.$$

A knowledge of θ enables us to determine the velocity in the liquid.



The velocity has been determined for four frequencies, as outlined in the accompanying table.

ULTRASONIC VELOCITIES OF POTASSIUM CHLORIDE SOLUTIONS AT 24° C

Percentage of potass. chloride	2·5 Mc./s.		2·25 Mc./s.		1·25 Mc./s.		0·625 Mc./s.	
	θ_t	V_t	θ_t	V_t	θ_t	V_t	θ_t	V_t
1	57·0°	1·692	57·2°	1·680	56·1°	1·660	55·6°	1·650
2	57·1°	1·659	54·6°	1·629	53·8°	1·615	53·2°	1·602
3	59·4°	1·720	56·1°	1·660	55·1°	1·640	54·3°	1·625
4	57·4°	1·684	58·8°	1·710	66·2°	1·830	67·7°	1·849
5	69·7°	1·876	68·9°	1·866	67·9°	1·853	66·5°	1·834
6	69·6°	1·875	67·7°	1·850	66·7°	1·836	64·7°	1·808
7	66·2°	1·830	65·1°	1·814	63·9°	1·796	62·9°	1·780
8	63·9°	1·795	63·4°	1·788	62·4°	1·772	61·7°	1·760
9	62·7°	1·776	62·1°	1·768	61·3°	1·754	60·7°	1·744
10	61·8°	1·763	60·7°	1·744	60·0°	1·732	59·7°	1·726

It will be seen from the results in the table and from the graph that the ultrasonic velocities show anomalous behaviour in the region of negative viscosity (1–6 per cent solution); hence, it may be useful to correlate the ultrasonic velocity data, or in other words the compressibility data, of electrolyte solutions with the negative viscosity.

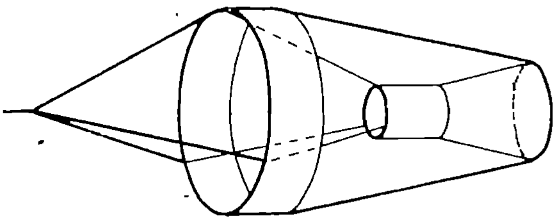
A High-speed Tow-net

IN order to investigate the changes in the distribution of young fish in the Clyde sea area it was necessary to obtain on each of a series of dates numerous samples of the population over a large area. To cover this area it was necessary for the research vessel to travel at full speed for as much as possible of the time available. This precluded the use of conventional tow-nets or trawls at set stations. Further, an apparatus like the Hardy plankton recorder would filter too small a volume of water to catch a significant number of young fish. Sheard[1] has described a net which appeared to be of the type required, in which the bucket is dispensed with and the tail of the net fliped (turned in on itself).

An ordinary plankton net was modified on this plan. The dimensions of the original net were: diameter of mouth 46 cm., calico collar 15 cm. long, silk (26 meshes per inch) 94 cm. long, bucket-sleeve 12 cm. in diameter and 17 cm. long. A metal ring was sewn into the end of the sleeve and three toggled bridles 42 cm. long attached to this ring. The tail of the net was fliped and the three toggles passed through the eye-splices of the main bridles of the net, as shown in the diagram. The bridles were shackled to a spring hank rove a fathom and a half above a cable depressor[2], on the trawl warp, and trials showed that it could be towed successfully at speeds of at least 7 knots. The general performance of the gear was found to be very satisfactory; there was no inclination to yaw and no frontal wave was observed.



By towing two such nets alternately, for four miles at a time, 5 m. below the surface, it has been possible to obtain samples continuously along the course of a 68-mile cruise. At the time of writing, each of the two nets employed has been towed for more than 160 miles without signs of undue strain. The catches which have already been obtained and analysed contained thirty-seven species, including up to 250,000 *Calanus* and 3,000 fish eggs per haul, sprats of up to 9 cm. in length and a wide variety of post-larval fish. Although more of these organisms were damaged than is usual in a normal tow-net catch, all but a few were easily identifiable, and indeed the majority of the catch was still alive when brought on board. Tests of the efficiency of the nets are in hand, and preliminary results indicate that their catching power is closely comparable with that of a tow-net of conventional design. Nets of various diameters and mesh sizes are also being tested, and the possibility of fishing at greater depths investigated.

Beet Yellows Virus

SEVERAL plant viruses have been found to occur as elongated particles of variable length and 10–15 mμ in width. Leyon[1] has published electron micrographs showing such rod-like particles with a width of about 10 mμ in sap from plants infected with beet yellows virus and in the specific precipitates produced by mixing the sap with its antiserum. We have also found rods in these two kinds of preparation. They do not occur in sap from healthy beet plants, and by analogy with other viruses which have been purified it could readily be assumed that the rods are the virus particles themselves. There are, however, other factors which make this assumption less tenable and suggest that the rods are not the only anomalous component in sap from infected plants.

With the appropriate antiserum, clarified sap from sugar beet plants infected with beet yellows virus gives specific precipitates that appear to be of the somatic type. Their precise character is difficult to determine when working with unfractionated material; but the general behaviour in precipitin tests resembles that of viruses with spherical rather than rod-shaped particles. Precipitates are obtained up to dilutions of 1/64, which by analogy with bushy stunt virus would suggest a specific antigen of concentration about 100 mgm./l.[2,3]. By contrast, only a few rod-like particles can be seen in electron microscope mounts made from clarified sap; and although the concentration cannot be determined accurately, it seems unlikely that it exceeds 1 mgm./l.[3]. It appears, therefore, that the rods can only amount to a small proportion of the specific antigen.

Further evidence for this view has been given by experiments on the effect of freezing sap from infected plants. Freezing had no detectable effect on the precipitin titre with antiserum; but after this treatment no rod-shaped particles have been found, either in clarified sap or in resuspended antiserum precipitates.

The evidence suggests that sap from infected plants contains at least two kinds of specific particles. One of these is the rod which can be seen with the electron microscope. The other probably occurs in much higher concentration; its size and shape are so far unknown; but the character of the precipitin reaction suggests that it may be spherical. Clarified sap from healthy sugar beet plants contains large quantities of spherical particles resolvable with the electron microscope[3], and it may be that the second antigen component resembles these. Alternatively, it may have particles too small to be resolved in existing electron microscopes.

The relationship between the components is unknown. Possibly the rods are an alternative form of the spherical particles, a phenomenon known with some other viruses, or perhaps the two components are quite distinct, one being the infective particle and the other a product of the disease.

A Rare Alga from Stonehenge

During a brief stay in England last year, towards the end of June a visit was paid to Stonehenge. It was noticed that several small holes in one of the fallen stones near the centre of the Circle contained green-coloured water, and since I am particularly interested in the flora of such small rain-water pools, permission to take samples was sought and readily granted. Water was spooned up, concentrated in a small freshwater plankton collecting net, and small quantities of the concentrate transferred to comparatively large jars. The following evening, on reaching my headquarters in Cheltenham, the samples were examined and most surprisingly proved to be very rich, active and nearly pure unialgal growths of *Hæmatococcus drœbakensis* Wollenweber[1]. I believed then that this alga was known only from pools in granite on a small island near Drobak in Norway; I have learnt since that there is one doubtful record from Wales.

This pretty little alga is most distinctive, bright green, with two pyrenoids placed symmetrically at opposite poles of the protoplast, across the centre of which is a clear, colourless zone; when grown in a rich nutrient solution, however, the latter is more or less completely obliterated by the extension of the chloroplast, while the whole protoplast becomes densely granular and much darker in colour.

Unlike the ubiquitous *Hæmatococcus lacustris*, in which reproduction is in general exclusively asexual, *H. drœbakensis* after a period of similar active asexual reproduction regularly enters a sexual phase, producing isogametes which on liberation conjugate to form zygotes. The whole process can be completed on agar and the resultant zygospores kept for months—at the time of writing I have a fresh series of active cultures raised from zygospores formed on agar last November. The alga is easily grown in culture, a rich growth being obtainable from the resting spores in a few days, and should prove invaluable to teachers of botany and biology as an example of a unicellular alga, for the study of both structure and behaviour and of reproduction by asexual and sexual methods.

Material was sent to Dr. E. F. Pringsheim, and I understand that *Hæmatococcus drœbakensis* has now been added to the collection of pure cultures of algæ maintained by him in the Botany School at Cambridge.

Changes in the Colour Sensitivity of the Eye with Posture

I refer to J. N. Aldington's letter in the issue of *Nature* of July 14.

My attention was directed to apparent change of colour sensitivity of the eye with its position by my sister—an artist. She pointed out to me that if the head were held sidewise, that is, with the line joining the eyes vertical instead of horizontal, all colours in a landscape appeared to be intensified. She was in the habit of using this aid in the course of her work.

On trying the method myself, I also noticed an intensification, and more particularly in the blue of a haze in the distance.

It may, of course, be the case that there is, in fact, no greater colour receptivity in the eye in this position, but that the attention is not so much distracted by form and detail in such circumstances and so colour gets a larger share of attention than it otherwise would have. The landscape certainly seemed more vague when viewed in this position.

The effects mentioned by Dr. J. N. Aldington in *Nature* of July 14, p. 86, and that described above are probably connected.

A. Blackie

Khandala Hotel,
Blackheath,
London, S.E.3.
July 19.

I was introduced some years ago, by a friend who lives in Cornwall, to a way of looking at the landscape by leaning as far to one side as possible. In this position after a short while the view takes on a much sharper impression, particularly hills and trees against the sky which appear to be seen in much greater detail.

The observation of J. N. Aldington (*Nature*, July 14, p. 86) that the colour sensitivity of the eyes differs when the two eyes are in different horizontal planes suggests a possible explanation of this phenomenon.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Tuesday, September 25—Thursday, September 27

DUBLIN INSTITUTE FOR ADVANCED STUDIES (in the School of Cosmic Physics, 5 Merrion Square, Dublin).—Colloquium on "Recent Advances in the Study of Cosmic Radiation".

Wednesday, September 26

PHYSICAL SOCIETY, COLOUR GROUP (in the Physics Department, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 3 p.m.—Mr. H. G. W. Harding: Demonstration of a Visual and a Photoelectric Portable Colour Temperature Meter; Report on the Decisions reached, on matters of interest to the Colour Group, at the Stockholm Meeting of the Commission Internationale de l'Eclairage.

Wednesday, September 26—Friday, September 28

NATIONAL SMOKE ABATEMENT SOCIETY (at the Winter Gardens, Blackpool).—Eighteenth Annual Conference.

Thursday, September 27

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. W. B. Roantree: "Work in High Air Temperatures in a Fire in Mysore Mine, Kolar Gold Field".

Thursday, September 27—Friday, September 28

SOCIETY OF CHEMICAL INDUSTRY, FOOD, AGRICULTURE and FINE CHEMICALS GROUPS (at the Wellcome Research Institution, 183–193 Euston Road, London, N.W.1), at 10.30 a.m. each day.—Conference on "Problems Arising from the Use of Chemicals in Food".

Friday, September 28

HOSPITAL PHYSICISTS' ASSOCIATION (in the Lecture Room, Department of Anatomy, The University, Downing Street, Cambridge), at 8.15 p.m.—Dr. L. H. Gray: "Actions of Radiations on Living Cells—1946 and After" (Second Douglas Lea Memorial Lecture).*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

AREA SUPERVISOR (with a degree in science or the N.D.D. or N.D.D.H.) at Beverley, Halifax, Reading and Starcross, and an ASSISTANT AREA SUPERVISOR (with a degree in science or the N.D.D. or N.D.D.H.) at Newcastle-under-Lyme and Nottingham, in the National Milk Testing Service—The Secretary, Ministry of Agriculture and Fisheries, Room 406, 23–25 Soho Square, London, W.1 (September 29).

BIOCHEMIST FOR BIOCHEMICAL DEPARTMENT of the Group Laboratory—The Secretary, Stepney Group Hospital Management Committee, Raine Street, London, E.1 (September 29).

LECTURER IN PHYSICAL AND INORGANIC CHEMISTRY at the Rutherford College of Technology—The Director of Education, City Education Office, Northumberland Road, Newcastle-upon-Tyne 1 (September 29).

LECTURER TO TEACH PHYSICS to degree standard, and an ASSISTANT (Grade A) TO TEACH ELEMENTARY PHYSICS up to the standard of the General Certificate of Education (Advanced Level)—The Clerk to the Governors, Woolwich Polytechnic, Woolwich, London, S.E.18 (September 29).

PHYSICAL CHEMIST IN THE RESEARCH BRANCH, Chief Engineer's Department, London, to work in a small team engaged in research on the corrosion of steel at boiler pressures—The Secretary's Office (Establishments), Applications Section, British Electricity Authority, British Electricity House, Great Portland Street, London, W.1, quoting AE/199 (September 29).

SENIOR EXPERIMENTAL OFFICERS, EXPERIMENTAL OFFICERS and ASSISTANT EXPERIMENTAL OFFICERS at Admiralty experimental establishments in the vicinity of London, Baldock, Greenock, Haslemere, Portsmouth, Rosyth and Weymouth: MECHANICAL ENGINEERS (Ref. C.632/50A) with research and development experience in light mechanisms, ELECTRICAL ENGINEERS (Ref. D.368/50A) with experience in telecommunications, radar, electronics or light electrical mechanisms, and PHYSICISTS (Ref. A.335/50A) interested in general physical problems, electronics or acoustics—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 29).

SENIOR LECTURER IN EXPERIMENTAL PHARMACOLOGY—The Secretary of University Court, The University, Glasgow (September 29).

SENIOR LECTURER or LECTURER IN MATHEMATICS at Gordon Memorial College, Khartoum—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 29).

LECTURER IN NUTRITION at the University of Otago (School of Home Science), New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 30).

ASSISTANT EXPERIMENTAL OFFICERS (including BIOLOGISTS) in various Government Departments and divided between (*a*) mathematical and physical sciences, (*b*) chemistry and metallurgy, (*c*) engineering subjects, and (*d*) miscellaneous (including, for example, geology, library and technical information services)—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting No. 3068 (October 1).

PLANT PATHOLOGIST to assist in the subediting and making of abstracts—The Director, Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey (October 1).

PROFESSIONAL ENGINEERS (general service class, main and senior grades) in Government Departments (at present in the Admiralty and in the Prison Commission)—The Secretary, Civil Service Commission, Trinidad House, Old Burlington Street, London, W.1, quoting No. S 86/51 (October 1).

PRINCIPAL SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics, and knowledge of electro-acoustics and electronics with experience in the planning of research) at the R.A.F. Acoustics Laboratory—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting No. S.1063/51 (October 4).

PROFESSOR OF VETERINARY MEDICINE, PHARMACOLOGY AND MEAT INSPECTION at the Veterinary College, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (October 5).

SCIENTIST, Grade III (with an honours degree in either geology or botany) IN THE COAL SURVEY LABORATORY at Sheffield for work on the palæobotany of coal and the correlation of seams—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/374 (October 13).

SCIENTISTS, Grade III (with honours degree in chemistry), IN THE COAL SURVEY LABORATORIES at Chester and Newcastle-upon-Tyne—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/376 (October 13).

SENIOR RESEARCH OFFICERS (2) IN THE SECTION OF METEOROLOGICAL PHYSICS, Highett, Victoria (one officer will engage in studies of the general circulation of the atmosphere, the other in problems of a dynamic-synoptic nature)—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3564 (October 13).

SENIOR MARKETING OFFICER (with a university degree in horticulture or agriculture, and wide experience of commercial methods of marketing horticultural or agricultural produce, including livestock)—The Secretary, Department of Agriculture for Scotland (Room 266), St. Andrew's House, Edinburgh 1 (October 15).

ELECTRICAL INSPECTOR OF MINES AND QUARRIES—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4075/51 (October 25).

LECTURER (with a degree in biochemistry and/or organic chemistry, and experience in the analysis of foods, including dairy products) IN AGRICULTURAL BIOCHEMISTRY (Dairy Chemistry) at the Massey Agricultural College, Palmerston North, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

CHAIR OF PHYSICAL CHEMISTRY in the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 12).

ASSISTANT EXPERIMENTAL OFFICER (with degree or diploma in agriculture, and practical knowledge of general farming) with aptitude for clear and concise self-expression in writing, and an ASSISTANT (Scientific), with practical farming experience and experience of handling machines in the field—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds.

BIOLOGIST (with good honours degree) for radio-biological research laboratory—The Secretary, South Manchester Hospital Management Committee, Christie Hospital and Holt Radium Institute, Manchester 20.

CHEMICAL ENGINEERS (Principal Scientific Officer grade) at a Ministry of Supply research and development establishment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.651/51A.

CHEMIST mainly for research analytical work—The Director of Research, Research Council of the British Whiting Federation, 245 Ampthill Road, Bedford.
